PREFACE

The advancements in the principles of surgery, the extension of the bounds of surgical procedures and the contributions of the basic sciences to surgical therapy continue to multiply rapidly. A modern textbook of surgery must be revised frequently to keep abreast of these changes.

In the relatively short time devoted to the presentation of surgery in a medical school curriculum, it is impossible for a student to acquire the knowledge he must have to become a surgeon. In fact, progress in surgery and education of the public have progressed to the point where the medical profession and many laymen recognize that a medical school diploma and a state license to practice, obtained after a year's internship, do not qualify an individual to perform surgical operations.

This textbook of surgery strives to place before the student an interestingly told story of the facts and principles which should form the basis for his education in surgery, so as to stimulate him to continue his self-education throughout his professional life. Each contributor to this seventh edition has aimed to present his subject in such a way that it will stimulate the young and older students of surgery alike to read further. In his own style of teaching and expression, each author has attempted to create a desire in the reader to learn more about the subject presented. Surgery is the *art* of the application of anatomy, physiology, bacteriology, pathology, biochemistry, pharmacology and other sciences to the best care of the patient. Each individual must strive to become a better surgeon by educating and improving himself in the complexities of judgment, responsibility and decision which each patient's problem presents.

The many additions to surgical knowledge have made it necessary to write volumes of text devoted to one particular specialty of surgical practice, if there is to be an encyclopedic coverage of the subject. This textbook makes no attempt to meet such a goal. It aims to aid the student of surgery of all ages to approach an understanding of surgical axioms properly. If each book becomes well thumb-marked, it will have accomplished its purpose. Reading references to recent and historical contributions in the literature have been provided to encourage the inquisitive and imaginative to seek further, so that they may construct their own understanding of the application of surgical principles.

In this edition, the chapters on Infections, The Abdominal Wall and Peritoneum, Surgery of Peptic Ulcer, The Urinary Tract, Male Reproductive System, The Foot, and Amputations have been completely rewritten by new authors. A section on Surgical Judgment has been added. Important changes and additions which reflect the most recent advances have been made in the other chapters, each of which has been thoroughly reviewed, and most have been heavily revised.

It cannot be emphasized too often that the education of a surgeon involves many fields of learning, as well as the appreciation of tradition, the only way by which wisdom may be passed on from generation to generation, and the realization that integrity, ideals, judgment, decision, action and the practice of the Golden Rule must often be upheld or exercised instantaneously by the surgeon.

Chicago, Illinois

LOYAL DAVIS

CONTRIBUTORS

WILLIAM E. ADAMS, M.D.

Raymond Professor of Surgery, University of Chicago School of Medicine, Attending Surgeon, Albert Merritt Billings Hospital, Chicago.

PAUL C. ADKINS, M.D.

Assistant Professor of Surgery, The George Washington University School of Medicine, Associate in Surgery, The George Washington University Hospital, Washington, D.C.

JOHN ADRIANI, M.D.

Professor of Surgery, Tulane University School of Medicine, Director, Department of Anesthesiology, Charity Hospital, New Orleans.

WILLIAM A. ALTEMEIER, M.D.

Professor of Surgery, University of Cincinnati College of Medicine; Chairman of the Department, Cincinnati General Hospital, Cincinnati.

FLETCHER AUSTIN, M.D.

Associate in Otolaryngology, Northwestern University Medical School; Attending Otolaryngologist, Passavant Memorial Hospital, Chicago

JOEL W. BAKER, M.D.

Consulting Surgeon, University of Washington School of Medicine; Chief of Surgery, Virginia Mason Hospital, Seattle.

SAM W. BANKS, M.D.

Associate Professor, Department of Orthopaedic Surgery, Northwestern University Medical School; Attending Orthopaedic Surgeon, Chicago Wesley Memorial Hospital, Chicago.

CLIFFORD J. BARBORKA, M.D.

Professor of Medicine, Northwestern University Medical School; Attending Physician, Passavant Memorial Hospital, Chicago.

CHARLES O. BECHTOL, M.D.

Professor of Orthopedic Surgery, University of California at Los Angeles, School of Medicine; Chief of Orthopedic Service, U.C.L.A. Hospital, Los Angeles.

JOHN L. BELL, M.D.

Assistant Professor of Surgery, Northwestern University Medical School; Attending Surgeon, Passavant Memorial Hospital, Chicago.

BRIAN BLADES, M.D.

Professor of Surgery, The George Washington University School of Medicine; Chief of Surgery, The George Washington University Hospital, Washington, D.C.

ARTHUR H. BLAKEMORE, M.D.

Associate Professor of Clinical Surgery, Columbia University College of Physicians and Surgeons, Associate Attending Surgeon, Presbyterian Hospital, New York.

JAMES BARRETT BROWN, M.D.

Professor of Clinical Surgery, Washington University School of Medicine, Associate Surgeon, Barnes Hospital, St. Louis

JOHN C. BURCH, M.D.

Professor of Gynecology, Vanderbilt University School of Medicine, Visiting Surgeon, St. Thomas Hospital, Nashville

WALTER W. CARROLL, M.D.

Associate Professor of Surgery, Northwestern University Medical School, Attending Surgeon, Passavant Memorial Hospital, Chicago

ROBERT L. CHALFANT, M.D.

Instructor of Obstetrics and Gynecology, Vanderbilt University School of Medicine, Chief, Obstetrics and Gynecology, Nashville General Hospital, Nashville

PAUL C. COLONNA, M.D.

Professor, Emeritus, Orthopaedic Surgery, University of Pennsylvania School of Medicine, Chief, Emeritus, Orthopaedic Surgery, Hospital of the University of Pennsylvania, Philadelphia

MURRAY M. COPELAND, M.D.

Professor of Oncology and Chairman of the Department, Georgetown University School of Medicine, Attending Surgeon, Georgetown University Hospital, Washington, D.C.

GEORGE CHILE, Jr., M.D.

Head of Department of General Surgery, Cleveland Clinic, Cleveland

ROBERT E. DESAUTELS, M.D.

Instructor in Surgery, Harvard Medical School, Junior Associate in Surgery (Urology), Peter Bent Brigham Hospital, Boston

JOHN M. DORSEY, M.D.

Professor of Surgery, Northwestern University Medical School, Chairman, Department of Surgery, Evanston Hospital, Evanston, Ill.

JAMES E. ECKENHOFF, M.D.

Professor of Anesthesiology, Schools of Medicine, University of Pennsylvania, Philadelphia

MINOT P. FRYER, M.D.

Associate Professor of Clinical Surgery, Washington University School of Medicine, Attending Staff, Barnes Hospital, St. Louis

CHARLES F. GESCHICKTER, M.D.

Professor of Pathology and Chairman of the Department, Georgetown University School of Medicine, Director of Laboratories, Georgetown University Medical Center, Washington, D.C.

FRANK GLENN, M.D.

Lewis Atterbury Stimson Professor of Surgery, Cornell University Medical College, Surgeon-in-Chief, The New York Hospital, New York

E. S. GURDJIAN, M.D.

Professor and Chairman of the Department of Neurosurgery, Wayne State University College of Medicine, Attending in the Department of Neurosurgery, Grace Hospital, Detroit

OWEN GWATHMEY, M.D.

Assistant Professor of Surgery, The George Washington University School of Medicine, Associate in Surgery, The George Washington University Hospital, Washington, D.C.

GEORGE A. HALLENBECK, M.D.

Associate Professor of Physiology and Surgery, Mayo Foundation, Graduate School, University of Minnesota, Consultant, Section of Surgery, Mayo Clinic, Rochester, Minnesota

J. HARTWELL HARRISON, M.D.

Clinical Professor of Genito-Urinary Surgery, Harvard Medical School; Urologic Surgeon, Chief of Service, Peter Bent Brigham Hospital, Boston.

HAROLD LAUFMAN, M.D.

Associate Professor of Surgery, Northwestern University Medical School; Attending Surgeon, Passavant Memorial Hospital, Chicago.

PAUL R. HAWLEY, M.D.

The Director, American College of Surgeons, Chicago.

HORACE T. LAVELY, JR., M.D.

Instructor in Gynecology, Vanderbilt University School of Medicine; Assistant Gynecologist, Vanderbilt University Hospital, Nashville.

FRANK HINMAN, JR., M.D.

Associate Clinical Professor of Urology, University of California School of Medicine, Chief of Urology, Children's Hospital, San Francisco.

GEORGE V. LE ROY, M.D.

Professor of Medicine, University of Chicago School of Medicine; Attending Physician, University of Chicago Clinics, Chicago.

CHARLES A. HUFNAGEL, M.D.

Professor of Surgery, Georgetown University Medical Center, Attending Surgeon, Georgetown University Hospital, Washington, D.C.

ROBERT B. LEWIS, M.D.

Deputy Chief, Pathology Branch, Allied Sciences Division, U. S. Army Biological Warfare Laboratories, Fort Detrick, Maryland.

EDWARD S. JUDD, M.D.

Professor of Surgery, Mayo Foundation, Graduate School, University of Minnesota, Consultant, Section of Surgery, Mayo Clinic, Rochester, Minnesota.

FRANKLIN LOUNSBURY, M.D.

Assistant Professor of Surgery, Northwestern University Medical School, Attending Surgeon, Passavant Memorial Hospital, Chicago.

ROBERT H. KENNEDY, M.D.

Formerly Professor of Clinical Surgery, New York University Post-Graduate Medical School, Consulting Surgeon, Beekman-Downtown Hospital, New York.

ROBERT A. MACBETH, M.D.

Associate Professor of Surgery, University of Alberta Faculty of Medicine, Attending Surgeon, University of Alberta Hospital, Edmonton, Canada.

THOMAS H. LANMAN, M.D.

Clinical Professor of Surgery, Emeritus, Harvard Medical School, Consultant in Surgery, Peter Bent Brigham Hospital, Boston.

IAN MACDONALD, M.D.

Clinical Professor of Surgery, University of Southern California School of Medicine; Senior Attending Surgeon (Tumor Surgery), Los Angeles County Hospital, Los Angeles.

WILLIAM A. LARMON, M.D.

Assistant Professor of Orthopaedic Surgery, Northwestern University Medical School, Attending Surgeon, Passavant Memorial Hospital, Chicago.

WALTER C. MACKENZIE, M.D.

Professor of Surgery and Chairman of the Department, University of Alberta Faculty of Medicine, Director of Surgical Services, University of Alberta Hospital, Edmonton, Canada.

SAMUEL F. MARSHALL, M.D.

Surgeon, Lahey Clinic, Boston

MICHAEL L. MASON, M.D.

Professor of Surgery, Northwestern University Medical School, Attending Surgeon, Passavant Memorial Hospital, Chicago

DONALD D. MATSON, M.D.

Associate Clinical Professor of Surgery, Harvard Medical School, Neurosurgeon, Children's Medical Center, Boston

FRANCIS M. McKEEVER, M.D.

Professor of Surgery (Orthopedic), University of Southern California School of Medicine, Senior Orthopedic Surgeon, Los Angeles County General Hospital, Los Angeles

CHESTER B. McVAY, M.D.

Clinical Professor of Surgery, University of South Dakota School of Medical Sciences, Chief of Surgery, Sacred Heart Hospital, Yankton, South Dakota

FRANCIS D. MOORE, M.D.

Moseley Professor of Surgery, Harvard Medical School, Surgeon-in-Chief, Peter Bent Brigham Hospital, Boston

ROBERT M. MOORE, M.D.

Professor and Chairman, Department of Surgery, University of Texas School of Medicine, Director, Surgical Services, University of Texas Medical Branch Hospital, Galveston

J. PIERMAN NESSELROD, M.D.

Assistant Professor of Surgery, Northwestern University Medical School, Attending Surgeon, Evanston Hospital, Evanston, Ill.

LOUIS B. NEWMAN, M.D.

Professor of Physical Medicine and Rehabilitation, Northwestern University Medical School; Chief, Physical Medicine and Rehabilitation Service, Veterans Administration Research Hospital, Chicago.

GERALD H. PRATT, M.D.

Associate Clinical Professor of Surgery, New York University College of Medicine, Attending Surgeon, St. Vincent's Hospital, New York

JAMES T. PRIESTLEY, M.D.

Professor of Surgery, Mayo Foundation, Graduate School, University of Minnesota, Consultant, Section of Surgery, Mayo Clinic, Rochester, Minnesota

EDWIN J. PULASKI, M.D.

Chief, Department of Surgery, U. S. Army Hospital, Fort Dix, N. J.

F. JOHNSON PUTNEY, M.D.

Clinical Professor of Laryngology and Broncho-Esophagology, Jefferson Medical College, Assistant Attending Broncho-Esophagologist, Jefferson Medical College Hospital, Philadelphia

I. S. RADWIN, M.D.

Vice President in Charge of Medical Affairs, University of Pennsylvania, Philadelphia

BRONSON S. RAY, M.D.

Professor of Clinical Surgery, Cornell University Medical College, Director, Department of Neurological Surgery, The New York Hospital, New York

DANIEL RUGE, M.D.

Associate in Surgery, Northwestern University Medical School, Attending Surgeon, Chicago Wesley Memorial Hospital, Chicago

ROBERT W. SCHNEIDER, M.D.

Instructor in Medicine, University of Oregon Medical School, Portland

HARRIS B. SHUMACKER, Jr., M.D.

Professor of Surgery and Chairman of Department, Indiana University School of Medicine; Chief of Surgical Service, Indiana University Medical Center, Indianapolis.

HAROLD A. SOFIELD, M.D.

Professor of Orthopaedic Surgery, Northwestern University Medical School; Chief Surgeon, Shriners' Hospital for Crippled Children, Chicago

JAMES K. STACK, M.D.

Associate Professor of Orthopaedic Surgery, Northwestern University Medical School; Attending Surgeon, Passavant Memorial Hospital, Chicago.

RICHARD W. STEENBURG, M.D.

Instructor in Surgery, Johns Hopkins Medical School, Assistant Chief of Surgery, Baltimore City Hospitals, Baltimore.

JEAN M. STEVENSON, M.D.

Associate Professor of Surgery, University of Cincinnati College of Medicine, Attending Surgeon, Cincinnati General Hospital, Cincinnati.

RICHARD H. SWEET, M.D.

Associate Clinical Professor of Surgery, Harvard Medical School; Visiting Surgeon, Massachusetts General Hospital, Boston.

DERRICK T. VAIL, M.D.

Professor of Ophthalmology and Chairman of Department, Northwestern University Medical School, Attending Surgeon, Passavant Memorial Hospital, Chicago.

RICHARD L. VARCO, M.D.

Professor, Department of Surgery, University of Minnesota Medical School, University of Minnesota Hospitals, Minneapolis.

ARTHUR B. VOORHEES, Jr., M.D.

Instructor in Surgery, Columbia University College of Physicians and Surgeons; Assistant Attending Surgeon, Presbyterian Hospital, New York.

THEODORE E. WALSH, M.D.

Professor of Otolaryngology, Washington University School of Medicine, Otolaryngologist in Chief, Barnes Hospital, St. Louis.

JOHN M. WAUGH, M.D.

Professor of Surgery, Mayo Foundation, Graduate School, University of Minnesota; Consultant, Section of Surgery, Mayo Clinic, Rochester, Minnesota.

J. E. WEBSTER, M.D.

Associate Professor of Neurosurgery, Wayne State University College of Medicine; Department of Neurosurgery, Grace Hospital, Detroit.

CLAUDE E. WELCH, M.D.

Clinical Associate in Surgery, Harvard Medical School, Visiting Surgeon, Massachusetts General Hospital, Boston.

FRANCIS E. WEST, M.D.

Chief, Orthopaedic Service, Mercy Hospital, San Diego.

HENRY M. WEYRAUCH, M.D.

Clinical Professor of Surgery (Urology), Stanford University School of Medicine; Attending Urologist, Stanford University Hospitals, San Francisco.

ALLEN O. WHIPPLE, M.D.

Valentine Mott Professor of Surgery, Emeritus, Columbia University College of Physicians and Surgeons, Consulting Surgeon, Presbyterian Hospital, New York.

JAMES C. WHITE, M.D.

Professor of Surgery, Harvard Medical School, Chief of Neurosurgical Service, Massachusetts General Hospital, Boston.

ROGER D. WILLIAMS, M.D.

Assistant Professor of Surgery, Ohio State University College of Medicine, Attending Surgeon, Ohio State University Hospital, Columbus.

BERNARD ZIMMERMANN, M.D.

Professor, Department of Surgery, University of Minnesota Medical School, University of Minnesota Hospitals, Minneapolis

JOHN C. WILSON, JR., M.D.

Assistant Clinical Professor of Orthopedic Surgery, University of Southern California School of Medicine, Attending Surgeon, Childrens Hospital, Los Angeles

ROBERT M. ZOLLINGER, M.D.

Professor and Chairman, Department of Surgery, Ohio State University College of Medicine, Chairman, Department of Surgery, Ohio State University Hospital, Columbus.

PUBLISHER'S FOREWORD

THE SAUNDERS COMPANY takes great pride in looking back over the long life and distinguished service to medicine of the Textbook of Surgery edited by Frederick Christopher, M.D., Emeritus Professor of Surgery at Northwestern University Medical School. It now takes equal pride in presenting the Seventh Edition of that text as a teaching instrument under the continuing editorial direction of Loyal Davis, M.D., Chairman of the Department of Surgery of Northwestern University Medical School.

The essential purpose of the text and the essential means to its accomplishment were initiated by Dr. Christopher and are here carried on in the Seventh Edition by Dr. Davis. In this new issue of the text Dr. Davis has given the separate contributors broader segments of surgery for discussion. This has resulted in a kinship of philosophy and identity of didactic purpose among the contributors which give the text much of the cohesiveness and force of a single-handed effort, but the method of presenting separate subjects by separate authors remains the same and achieves the same effect of authority and comprehensiveness.

One of the innovations of the Editor in the previous edition was preparation of the biographical sketches which appear beneath the names of each of the contributors to this Textbook, save his own. This one missing biography the publisher would like to fill in here.

Loyal Davis was born in Galesburg, Illinois, and received his education at Knox College and Northwestern University. As a Fellow of the National Research Council, he received his surgical training under Allen B. Kanavel and spent a year as a voluntary assistant in neurological surgery at the Peter

Bent Brigham Hospital in Boston. He returned to Northwestern University Medical School and assumed the Chairmanship of the Department of Surgery in 1932.

During World War II, he was the senior consultant in neurological surgery to the Chief Surgeon of the European Theatre of Operations from 1942 to 1944 and was one of the two surgeons from the United States who were members of the first surgical mission to Russia. His contributions in surgery, neurological surgery, medical education and literature are numerous. He has been Editor of Surgery, Gynecology and Obstetrics since 1938, and has been elected to honorary fellowships in the Royal College of Surgeons in England and the Royal College of Surgeons in Edinburgh and to the presidency of the American Surgical Association.

It may be imagined that the publishing problems in processing so large a text by so many authors are difficult. In these problems Dr. Davis has shown toward his associates and his publisher unflinching helpfulness and decisive judgment. It is due to his untiring effort that publication of the book has been achieved quickly and effectively.

Finally, the publisher would like to add a word of appreciation to the one indispensable person in the long, mysterious and complex process of transforming thoughts to words and words to printing. He is the contributor. It is on his work and his authority that this book rests. The text reflects his investigation, his clinical insight, his experience, his skill, his conclusions. This book through the contributor becomes a mirror of modern surgery, in which many act together in a common cause and in which the knowledge of all is freely called upon.

W. B. SAUNDERS COMPANY

HISTORY OF SURGERY

By ALLEN O. WHIPPLE, M.D.

ALLEN OLDFATHER WHIPPLE received his education at Princeton and Columbia Universities. He has served the former with distinction as a Trustee and the latter as Valentine Mott Professor of Surgery. While Director of the Surgical Service at Columbia Presbyterian Hospital of New York he pioneered in the surgery of the pancreas and spleen and actively encouraged and secured an intimate cooperation between the surgeon and the bacteriologist. His scholarly attainments have made him a valuable consultant to foreign countries in medical education. His equanimity and kindly spirit have given him an enviable position in American surgery.

Surgery has been defined as "That branch of Medical Science which treats of mechanical or operative measures for healing diseases, deformities and injuries", that is, surgery is a branch of medical science. It has to do with therapy carried out by the hands; its purpose is to heal.

Certainly surgery is the oldest branch of therapy. It began in prehistoric ages with primitive man, when in his struggle for existence he was continually in conflict with the animals he hunted, or that were hunting him, as well as with his human enemies. Wounds, incised and lacerated, and hemorrhage from them, demanded immediate treatment by some member of his family, or later of his tribe, who had the courage and the knowledge to deal with bleeding gaping wounds, by such crude methods as pressure and the application of moss and cobwebs. The first surgeon may have been a frantic mother rescuing her wounded child from one of the carnivores.

The history of surgery is a very long one. It is impossible, in one chapter, to give in any detail the evolution of the processes which have brought it to its eminence of

today or to name all the surgeons through historic ages who have had to do with its evolution. For this reason only certain categories and problems that appear to be most important in the development of the art and science of surgery will be discussed, in the hope that the medical student and the busy practicing young surgeon will be stimulated to read, in more detail, the story of surgery, as given in the texts and literature of that subject.

At the beginning it is important to appreciate that surgery has been, and still is, a more definite form of therapy than medicine and that the results, good or bad, are more convincing. The lesions that required surgery in the early historic and prehistoric periods had a definite etiology and were not ascribed, as were so many medical complaints, to demonic and theurgic causes. Through the ages attempts to demean surgery as a manual act, to be assigned to ignorant barbers and menials, have ultimately failed, because injury, wounds, profuse hemorrhage and deformities could not be exorcised or cured by incantations or the administration of a noxious polypharmakon.

the sick and crippled. The monks took over the care of these people, using incantations and prayers in treating them, and reconciling them to the belief that illness and disability were the inevitable result of God's will.

Wide separation of medicine and surgery resulted from care of the sick by the monks and surgical treatment by the barbers attached to the monasteries. To the latter's original duties of tonsuring the monks and clergy had been added the task of blood-letting, which eventually led to their role as surgeons.

During the Dark Ages of the fourth to the tenth century, medicine became more and more sterile because of its divorce from the definite disciplines of surgery. Because the latter was left in the hands of crude and uneducated barbers, it in turn degenerated into a low estate, with fugitive lithotomists and herniotomists doing their hit-and-run operations under the worst of conditions.

However, by the twelfth century, because wars continued and injuries occurred among the civilians, the services of the surgeon became urgent and necessary, and in a few cases made the surgeon aware of the natural processes of wound healing.

Hugo of Lucca (in the 1100 A.D. period) was an Italian army surgeon who believed in the simple nonsuppurative method of treating wounds. He taught this doctrine to his son and pupil Theodoric (1205-1296). In Theodoric's Treatise on Surgery he states Hugo's and his own views on the subject—"For it is not necessary, as Roger and Roland have written, as many of their disciples teach, and as all modern surgeons profess, that pus should be generated in wounds. No error can be greater than this. Such a practice is indeed to hinder Nature, to prolong the disease, and to prevent the conglutination and consolidation of the wound."

Hugo and Theodoric denounced the galenic tradition and its polypharmacy with suppurative measures in treating wounds and taught healing by first intention. For fresh wounds they rejected oils, salves and poultices and advocated washing the wound with wine, removal of every foreign particle, and brought the wound surfaces together with a lint pad, soaked in wine, placed over the apposed edges. In old wounds they tried to obtain union by cleansing them and refreshing the wound margins.

Two of the early French surgeons must be mentioned in connection with this subject, because one supported primary wound healing, and the other did more than any one

else to denounce it and delay its acceptance for the next 500 years. The first of these two surgeons, Henri de Mondeville, was educated at Montpellier and later studied with Theodoric in Italy, where he obtained his ideas about treating wounds which he strongly advocated. His writings were full of biting wit and withering sarcasm against galenic tradition. For this reason they were displeasing to the Church and the clerical physicians, who were rigid in their acceptance of galenic lore, and for a long time his writings were not published. Satirically, Henri declared that God did not exhaust His creative powers in making Galen, and ridiculed the clerics who were supposed to know surgery by the Grace of God. He resented their jibes that surgery is merely a handicraft, and said that if the mind must inform the hand in its work, the hand likewise instructs the mind in its interpretation of the function of the hand. He was a keen observer of the rich and the poor. He stated, "Some of them [the rich] are as mean in their fat bellies as they are in their fat purses. If you have operated conscientiously on the rich for a proper fee, and on the poor for charity, you need not play the monk nor make pilgrimages for your soul."

The method of treating wounds which Henri preached and practiced was as follows:

Wash the wound scrupulously from all foreign matter, use no probes, no tents except under special conditions; apply no oils or irritating matters, avoid the formation of pus, which is not a stage of healing but a complication. Wounds dry much better before suppuration than after it. When your dressings have been carefully applied do not interfere with them for several days, keep the air out, for a wound exposed to the air suppurates.

This certainly antedated Lister.

With the new method you will have no stinks, shorter convalescence and clean thin scars. If treated on Theodoric's and my instructions, every simple wound will heal without any notable quantity of pus. Many surgeons know how to cause suppuration, few how to heal a wound. (He gives instructions on how to operate—) Always put your needles and thread in order before you operate, and the thread not in a tangle, for blood will not wait. Needles must be of various sizes, sharp and clean, or they will infect the wound.

The second French surgeon, Guy de Chauliac, is given special attention because of the baleful influence he had on subsequent generations on the treatment of wounds. He lived in the fourteenth century, studied in Bologna, Montpellier and Paris and was aware of the teachings of Theodoric and of

Because so many surgical procedures are concerned with wounds, accidentally acquired or made by the surgeon himself, the first category to be discussed is Wound Care and Wound Repair. This will be followed by Hemostasis, Anesthesia and Training of the Surgeon.

WOUND CARE AND WOUND REPAIR

From Antiquity into Nineteenth Century. The first authentic record we have on the care of wounds is from Egypt. The Edwin Smith Papyrus is considered to be a copy of one or more earlier ones written some 3000 years B.C. In this papyrus the treatment of wounds is mentioned. It consisted of holding the wound edges together with bandages to be obtained from the embalmers. In the Ebers Papyrus, written about 1550 B.C., which was a compilation of texts of earlier periods, the treatment of wounds is recorded as consisting of maintaining apposition of wound edges by means of linen bandages soaked in myrrh and honey, to be removed after four days.

Sumerian, Babylonian and Chinese medicine made no contribution to the subject. The Chinese used scarification and the actual cautery and cupping in their surgery. The two famous Hindu surgeons and physicians, Charaka and Susruta, of uncertain date, and their teachings are described in the Charaka Samhita (second century? A.D.) and the Susruta Samhita (fifth century? A.D.). The latter describes some 121 surgical instruments of various kinds. The use of the ligature was apparently unknown. Amputations were done and hemorrhage was controlled by pressure, cautery and boiling oil.

The first record dealing with the care of the wound by the Greeks is to be found in the homeric poems, the Iliad and the Odyssey. According to Daremberg, some 141 wounds are mentioned in these poems, for they had to do with warfare. The treatment of wounds caused by arrows, swords and spears consisted of the removal of the weapon, enlarging the wound by knife dissection if necessary, cleansing of the wound, and the application of astringent powders, compresses and bandages.

The temple of Asclepius at Cos was one of many temples of Aesculapius, the Greek god of medicine. It was in Cos that the great physician, Hippocrates, was born in 460 B.C., and it is from the school of the temple of Asclepius that the famous Hippocratic Oath is believed to have been written by him. It is entitled, 'On

Wounds and Ulcers.' It was his freedom from superstition and mysticism, as well as his honest and objective observation of symptoms and signs, that makes Hippocrates the first great physician and surgeon in history.

With the record of hippocratic surgery and Hippocrates' recognition of the advantages of primary wound healing began a bitter controversy between those advocating healing by first intention and the protagonists of suppurative wound healing—one that continued for centuries, with the advocates of laudable pus dominating wound care most of the time until Lister's epoch-making discoveries.

The famous Alexandrian School, founded in the third century B.C., contributed soundly to anatomy because of the vivisections and autopsies which were permitted there at that time. But the discoveries of Herophilus and Erasistratus in anatomy did not result in any great contribution to the problem of wound repair or to the subsequent controversy. However, the surgery done at the Alexandrian School was transmitted to the Greco-Roman period. It was here that the ligature was first used, as will be mentioned later.

Galen (131–201 A.D.), the great figure in Roman medicine, was born in Pergamon, Asia Minor, and spent his earlier years of practice in that city, where he cared for the gladiators in the gymnasium. He was thus able to observe fresh extensive incised wounds, and found that if they were irrigated with wine and closed with linen sutures they healed promptly without the formation of pus, and that many of the gladiators were able to resume their occupations. Unfortunately for posterity, Galen's early surgical experiences and interests were forgotten in his later polypharmacy. But in his original anatomic studies he emphasized the importance of knowing the site and size of anatomic structures in dealing with wounds—"If under such circumstances one does not know the position of an important nerve or muscle, or of a large artery or vein, it can happen that one helps the man to death, or sometimes mutilates him, instead of saving him."

With the decline and fall of the Roman Empire and the rise of Christianity there took place a different attitude toward sickness and death. The dissolute customs and low morals of this late Roman period drove many men into monastic orders, and the monasteries and churches became hostels for

the sick and crippled. The monks took over the care of these people, using incantations and prayers in treating them, and reconciling them to the belief that illness and disability were the inevitable result of God's will.

Wide separation of medicine and surgery resulted from care of the sick by the monks and surgical treatment by the barbers attached to the monasteries. To the latter's original duties of tonsuring the monks and clergy had been added the task of blood-letting, which eventually led to their role as surgeons.

During the Dark Ages of the fourth to the tenth century, medicine became more and more sterile because of its divorce from the definite disciplines of surgery. Because the latter was left in the hands of crude and uneducated barbers, it in turn degenerated into a low estate, with fugitive lithotomists and herniotomists doing their hit-and-run operations under the worst of conditions.

However, by the twelfth century, because wars continued and injuries occurred among the civilians, the services of the surgeon became urgent and necessary, and in a few cases made the surgeon aware of the natural processes of wound healing.

Hugo of Lucca (in the 1100 A.D. period) was an Italian army surgeon who believed in the simple nonsuppurative method of treating wounds. He taught this doctrine to his son and pupil Theodoric (1205-1296). In Theodoric's *Treatise on Surgery* he states Hugo's and his own views on the subject—"For it is not necessary, as Roger and Roland have written, as many of their disciples teach, and as all modern surgeons profess, that pus should be generated in wounds. No error can be greater than this. Such a practice is indeed to hinder Nature, to prolong the disease, and to prevent the conglutination and consolidation of the wound."

Hugo and Theodoric denounced the galenic tradition and its polypharmacy with suppurative measures in treating wounds and taught healing by first intention. For fresh wounds they rejected oils, salves and poultices and advocated washing the wound with wine, removal of every foreign particle, and brought the wound surfaces together with a lint pad, soaked in wine, placed over the apposed edges. In old wounds they tried to obtain union by cleansing them and refreshing the wound margins.

Two of the early French surgeons must be mentioned in connection with this subject, because one supported primary wound healing, and the other did more than any one

else to denounce it and delay its acceptance for the next 500 years. The first of these two surgeons, Henri de Mondeville, was educated at Montpellier and later studied with Theodoric in Italy, where he obtained his ideas about treating wounds which he strongly advocated. His writings were full of biting wit and withering sarcasm against galenic tradition. For this reason they were displeasing to the Church and the clerical physicians, who were rigid in their acceptance of galenic lore, and for a long time his writings were not published. Satirically, Henri declared that God did not exhaust His creative powers in making Galen, and ridiculed the clerics who were supposed to know surgery by the Grace of God. He resented their jibes that surgery is merely a handicraft, and said that if the mind must inform the hand in its work, the hand likewise instructs the mind in its interpretation of the function of the hand. He was a keen observer of the rich and the poor. He stated, "Some of them [the rich] are as mean in their fat bellies as they are in their fat purses. If you have operated conscientiously on the rich for a proper fee, and on the poor for charity, you need not play the monk nor make pilgrimages for your soul."

The method of treating wounds which Henri preached and practiced was as follows:

Wash the wound scrupulously from all foreign matter, use no probes, no tents except under special conditions; apply no oils or irritating matters; avoid the formation of pus, which is not a stage of healing but a complication. Wounds dry much better before suppuration than after it. When your dressings have been carefully applied do not interfere with them for several days, keep the air out, for a wound exposed to the air suppurates.

This certainly antedated Lister.

With the new method you will have no stunks, shorter convalescence and clean thin scars. If treated on Theodoric's and my instructions, every simple wound will heal without any notable quantity of pus. Many surgeons know how to cause suppuration, few how to heal a wound. (He gives instructions on how to operate—) Always put your needles and thread in order before you operate, and the thread not in a tangle, for blood will not wait. Needles must be of various sizes, sharp and clean, or they will infect the wound.

The second French surgeon, Guy de Chauliac, is given special attention because of the baleful influence he had on subsequent generations on the treatment of wounds. He lived in the fourteenth century, studied in Bologna, Montpellier and Paris and was aware of the teachings of Theodoric and of

Because so many surgical procedures are concerned with wounds, accidentally acquired or made by the surgeon himself, the first category to be discussed is Wound Care and Wound Repair. This will be followed by Hemostasis, Anesthesia and Training of the Surgeon.

If you have operated conscientiously on the rich for a proper fee, and on the poor for charity, you need not play the monk nor make pilgrimages for your soul."

The method of treating wounds which Henri preached and practiced was as follows:

Wash the wound scrupulously from all foreign matter, use no probes, no tents except under special conditions, apply no oils or irritating matters; avoid the formation of pus, which is not a stage of healing but a complication. Wounds dry much better before

to the air suppurates.

This certainly antedated Lister.

With the new method you will have no stinks, shorter convalescence and clean thin scars. If treated on Theodoric's and my instructions, every simple wound will heal without any notable quantity of pus. Many surgeons know how to cause suppuration, few how to heal a wound. (He gives instructions on how to operate—) Always put your needles and thread in order before you operate, and the thread not in a tangle, for blood will not wait. Needles must be of various sizes, sharp and clean, or they will infect the wound.

The second French surgeon, Guy de Chauliac, is given special attention because of the baleful influence he had on subsequent generations on the treatment of wounds. He lived in the fourteenth century, studied in Bologna, Montpellier and Paris and was aware of the teachings of Theodoric and of

Henri de Mondeville when he wrote his famous Text-book on Surgery. In his teachings in this book he was deaf to the message of primary wound healing and adhered to the galenic tradition and advocated the suppurative treatment of wounds. So authoritative was his textbook that for the next 500 years laudable pus was considered essential, even up to the time of Lister.

In explanation of the belief in laudable pus it must be stated that in the wounds which were infected with virulent bacteria, the patients died before suppuration developed, whereas patients with wounds infected with the less virulent pyogenic organisms survived after suppuration developed. So pus was considered laudable.

The discovery of gunpowder and its use in warfare introduced a new type of wound which caused endless controversy as to its nature. Some claimed that these wounds were poisoned by the gunpowder on the invading missiles. Others, in the minority, denied the poisonous theory. But the severe nature of these injuries occurring in the extremities, frequently associated with compound fractures, made amputation mandatory. Such wounds, with or without amputation, were treated with boiling oil and the actual cautery.

Ambroise Paré, who will be discussed more fully later because of his restoration of the ligature in the handling of hemorrhage was interested in the subject of wound healing and did much to improve it with his use of the ligature, but he still could not get away from the employment of material which interfered with Nature's healing processes and had his pet puppy fat salve. He continued to follow much of Guy de Chauliac's teachings and induced suppuration in the treatment of his wounds.

The anatomic studies of Leonardo da Vinci and of Vesalius, as well as the discovery of the circulation of the blood by Harvey, broadened the fields of surgery extensively but did not restore the teachings of Hugo, Theodoric and Henri in their advocacy of primary wound healing. Even that greatest of English surgeons before Lister's time, John Hunter, in his studies of inflammation, did not solve the problem of wound infection which prevailed in his day and the first half of the nineteenth century.

During the latter part of the eighteenth century, because of the increased amount of surgery, the overcrowding of surgical wards, and especially because of the custom of the surgeons coming from the dissecting

rooms to the operating amphitheaters to perform their operations without sanitary precautions, the incidence of infection in all forms—erysipelas, gas gangrene, septicemia, pyemia—was appalling (as high as 80 per cent). In the maternity wards the incidence of puerperal sepsis was equally great.

Before the discovery of ether and chloroform, speed and sleight-of-hand work were the marks of a surgeon's competence. Cheselden is said to have performed a lithotomy in less than one minute and Liston a leg amputation in twenty-five seconds! At this rate it is easily understood that antiseptic precautions could not be considered. Both from the patient's and the surgeon's standpoint an operation was to be performed in the shortest time possible.

If wound infection could only be prevented what a blessing it would be to humanity! This idea must have occurred to every thoughtful surgeon in those dark days, as well as to the obstetrician. In fact, it was an obstetrician—Semmelweis (1818-1865)—who first demonstrated the efficacy of antiseptic solution in cleansing the hands. While working in the Vienna General Hospital he made a keen observation. In the maternity ward where the medical students, coming from the dissecting rooms, made vaginal examinations and took part in the deliveries, the mortality from puerperal sepsis was four times higher than it was in the ward attended by midwives. When one of his associates cut his hand in the dissecting room and died soon after of the symptoms of puerperal sepsis, Semmelweis was convinced that sepsis was the result of uncleanness. He introduced chlorinated water in the ward where the students worked, insisting that they wash their hands thoroughly in this solution before any examination or delivery. The incidence of puerperal sepsis dropped immediately to that of the ward attended by the midwives. Because his discoveries were not recognized until years later, he brooded over it and, after publishing his great work on the nature of puerperal sepsis in 1861, died insane. His name, however, will always be honored as that of the man who first demonstrated the means of preventing wound infection.

Dawn of Antiseptic and Aseptic Surgery. Two great men are responsible for smashing the specter of infection which had haunted the surgeon and physician for so many centuries.

The world figure, Louis Pasteur (1822-1895), was a chemist, but he founded the

science of bacteriology. By his epoch-making discoveries of the true nature of fermentation, especially as caused by lactic acid bacteria, he destroyed the doctrine of spontaneous generation of organisms, which had been so strongly advocated by Liebig and other chemists. He proved that wine fermented because of the presence and growth of minute organisms, and that if these were eliminated by heat, fermentation did not take place. His original researches in anthrax and hydrophobia alone would have made him world famous. His basic studies in the true nature of putrefaction in animal matter by the action of bacteria set the pattern and initiated the work which was to follow.

Joseph Lister (1827-1912) was a Quaker and had the good fortune of having an eminent microscopist as a father and an understanding and cooperative wife, the daughter of the famous Edinburgh surgeon, James Syme. After studying medicine at London University he decided to be a surgeon, and was accepted by Syme and became his very able house surgeon.

At Syme's suggestion, Lister stood for, and was appointed to the chair of surgery at Glasgow, where he carried on his epoch-making researches on the nature of infection in wounds and their prevention. When he first began his work in the Glasgow Infirmary, he was distressed to find that with every precaution then known his mortality in amputation cases was 45 per cent. He was greatly impressed by the fact that simple fractures healed kindly, but the compounded ones developed sepsis and required amputation; also, that if a wound healed without pus the patient did well. He became convinced that pus was caused by infection and if this could be prevented the patient would do well.

Lister, being a student of the literature, soon read of Pasteur's discoveries in lactic acid fermentation. He realized immediately that if infection could be prevented at the start pus would not form in the wound. Because the wound could not be sterilized by heat he looked for other means. He learned that in the city of Carlisle, sewage treated with carbolic acid did not putrefy. This led him to try the effect of carbolic acid in varying strengths as a disinfecting agent to combat germs which had invaded the operative field. He used various dressings saturated with dilute solutions of the acid and because he was sure that these bacteria were in the air and entered the wound, he had the operating room and the operative field

sprayed with a carbolic acid solution before each operation.

Lister began his work in antiseptics in 1865. The treatment of his first patient with a compound fracture did not succeed, but that of his second resulted in healing by primary union. During the next two years he accumulated an increasing number of successful operations and in 1867 published two revolutionary papers in the London Lancet, entitled: "On a New Method of Treating Compound Fracture, Abscess, etc., with Observations on the Condition of Suppuration" and "On the Antiseptic Principle in the Practice of Surgery." In these remarkable publications he demonstrated in convincing fashion the amazing improvement in wound healing by the use of his antiseptic techniques.

Strangely enough Lister's ideas did not receive immediate acceptance by the British surgeons, and men like Lawson Tate, who had remarkably good wound healing because he was very insistent on the thorough cleansing of his hands before he operated, ridiculed the "new fangled listerism." But by 1868 Lucas Championnière, in France, had followed Lister and the new doctrine was accepted by Nussbaum in Germany.

In 1877, Robert Koch, the great German bacteriologist, published his monograph, "The Cause of Infection in Wounds," in which he showed for the first time the specificity of the different kinds of bacteria which caused infection and that each organism had characteristics which gave distinct clinical pictures. More and more it became evident that antiseptics was only a partial solution of the problem of infection and that the prevention of the introduction of bacteria into the wound was more important than trying to kill the bacteria, or prevent their growth, after they had entered the wound—in other words, the principle of asepsis. Surgeons began to appreciate the fact that if the pathogenic organisms could be eliminated from the operative field the chances of clean wound healing would be far greater than was possible otherwise. The first of the antiseptic techniques of Lister to be discarded was the carbolic spray which was denounced by von Bruns, in 1880, in his pronouncement, "Fort mit der Spray." Von Bergmann realized that, if the living tissues of the patient could not be sterilized by heat, everything else which came in contact with the wound except the surgeon's hands could be, and so in 1886 he devised the method of steam sterilization which has become a *sine*

qua non in all modern operating rooms. It was Halsted who introduced the use of sterile rubber gloves, freeing the surgeon and his assistants from the onus of contaminating their hands. In 1900, Hunter, of the Charing Cross Hospital in London, was the first to introduce the use of the gauze mask by the operating team.

World recognition came to Lister while he was still active. After he moved from Edinburgh, where he had succeeded Syme, to the Professorship of Surgery in Kings College in London, he was the first surgeon to be made a peer of the British Empire. He was showered with honors from all over the world. He was justly called, "The Great Benefactor." Among his most outstanding characteristics were his innate modesty and his insistence on giving credit to the men who he thought had led to his discoveries in the causes of wound infection, especially Pasteur and Semmelweis.

With the discovery of the role of bacteria in wound infection and the benefits of previously established anesthesia, surgery made unprecedented progress. But even with the acceptance of asepsis in the leading surgical clinics of the world, infection of clean operative wounds continued, although to a far less degree to be sure, owing to factors not adequately appreciated. These were the inability to sterilize the skin, inadequate hemostasis, unnecessary tissue damage due to the use of heavy blunt-nosed hemostats which crushed the tissues surrounding the bleeding vessels, and especially the use of heavy grades of catgut ligature and suture material which acted as irritating foreign bodies and culture media for the bacteria which escaped the aseptic technique.

It was the great Swiss surgeon, Theodore Kocher, who first demonstrated the importance of the meticulous technique of wound repair. This consisted of minimum tissue damage attained by the use of finer ligature and suture material, the material being non-absorbable silk. In a period of seven weeks, in 1887, he found that in thirty-one patients upon whom operations were performed wound infection occurred in twenty-nine in whom catgut had been employed. When silk replaced catgut infections ceased. The paper in which he described this remarkable improvement in wound healing was published in an obscure Swiss journal and did not attract the attention it deserved.

One of Kocher's great admirers was William S. Halsted, the first Professor of Surgery at the Johns Hopkins Medical School. He

had been a brilliant rapid operator as a young surgeon in New York City, but during an enforced period of retirement and contemplation, before he went to Baltimore, he revised his ideas of surgical technique and surgical training, which resulted in his becoming a careful, deliberate operator, with a meticulous regard for minimizing tissue damage by the use of sharp knife dissection, fine pointed hemostats, fine needles and finer grades of silk than were previously employed for his ligature and suture material. Like Lister and Kocher he gave great attention to the study of wound healing and wound repair, and established the principle which after some twenty-five years of trial and error he described in a publication appearing in 1913.

Halsted's paper is so epoch making that several quotations are here included. He definitely improved on Kocher's technique. He stated

Our method of employing silk differs quite essentially from Professor Kocher's. The silk which we use is much finer than his, and we rely on transfixion to prevent the ligature from slipping.

I am unable to say precisely when it was that I definitely substituted silk for catgut. It must have been earlier than 1883, for in that year, or in 1882, Warmbrun, Quilitz & Co. of Berlin made for me, in glass, bobbins of my designing, to be held in the left hand of the operator during the act of ligating vessels.

I have employed them continuously from the time of their introduction to the present. Black silk was selected in preference to white because it was easier to see on the glass bobbins, and in the fresh wound, and more easily identified in the healed wounds.

The following winters, 1887-1889, in my experiments on the thyroid gland, I employed exclusively the black silk, just as we do to-day, ever since the opening of the Johns Hopkins Hospital twenty-five years ago.

The relatively high cost of catgut, its bulkiness, the inconveniences attending its use and sterilization, its inadequacy, the uncertainty as to the time required for its absorption, and the reaction which it excites in a wound, induced me to discard it for clean wounds, both of the human subject and of animals.

That surgeons obtained excellent results with silk even when gloves were not worn one may convince himself by the papers of Kocher, Hadenham and Hagler. Now that gloves are invariably worn, the results with silk, properly employed, are so perfect that I believe its adoption will ultimately become general.

This was a prophecy fulfilled many years later.

The surgeon who desires to use silk, and who, after giving it a trial, finds that the results are not as good as with catgut, may I think quite surely attribute his failure to himself—to faulty technique. By faulty technique I do not mean merely breaks in asepsis.

One should not of course use silk for ligating and suturing in the presence of infection. Nor should one

bring parts together under such degree of tension as to cause necrosis of the suture line, or interfere greatly with the blood supply, for nothing is gained by so doing, and decided harm may result. Healing is menaced when the circulation of the tissues to be united is impaired. . . . The silk to be employed should never be coarser than necessary. It is useless to employ a thread for suture which is stronger than the tissue itself. . . . A greater number of fine stitches is better, as a rule, than a few coarse ones . . . *Avoid if possible the combined use of silk and catgut in a wound.*

This last sentence he underlined but did not give reasons for the admonition. The significance of the statement lies in the fact that catgut predisposes to bacterial growth and if infection develops in such a wound the silk sutures may act as foreign bodies, to be extruded later.

Halsted's surgical philosophy regarding wound repair with silk is epitomized in his dictum, given without explanation, "Silk should not be used that does not break easily." Surgeons who have not used silk properly cannot understand this.

In this same paper, Halsted stated,

In the winter of 1889-1890—I cannot recall the month—the nurse in charge of my operating room complained that the solutions of mercuric chloride need and a domestic of her own and her husband's

tional gloves were ordered. . . . After a time the assistants became so accustomed to working in gloves that they also wore them as operators and would remark that they seemed to be less expert with the bare hands than with the gloved hands . . . Thus the operating in gloves was an evolution rather than an inspiration or happy thought. . . . Rubber gloves must be worn by all concerned in the operation

The use of the modern and recently discovered bacteriostatic and bacteriolytic antibiotics has revolutionized the treatment of medical and surgical localized and blood stream infections, but to depend upon the local instillation of these preparations and the shotgun doses of these antibiotics to replace careful aseptic and atraumatic wound repair is bad surgical practice. The normal period of wound repair by first intention—three to four days of lag period, followed by ten days of fibroplasia—cannot be improved or accelerated. Many attempts have been made to introduce so-called wound healing substances for shortening Nature's healing process. This was well illustrated during World War II, when the Committee on Burns and Contaminated Wounds of the Na-

tional Research Council was deluged by well-meaning, but ignorant, persons recommending everything from chlorophyll to Mexican jumping bean extract—all of which, of course, were useless—to be used in hastening the healing of war wounds. The surgeon's constant effort should be to eliminate the factors which interfere with and prevent Nature's normal processes of wound healing. These are tissue damage and the failure to remove damaged or dead tissue, failure to maintain the blood supply to the wound borders and the adjacent tissues; failure to prevent the accumulation of blood clot and exudate in and between the wound surfaces, which tend to keep the wound margins apart; the introduction of heavy suture and ligature material which act as foreign bodies, and failure to maintain asepsis.

With the great example of Lister in his epoch-making discoveries in wound infection in his laboratory, it is strange that it was not until 1923 that the first bacteriologic laboratory, as part of the surgical clinic, was organized at the Columbia Presbyterian Hospital. Dr. Frank L. Meleney, a trained surgeon and bacteriologist especially interested in wound infections, was in charge of this laboratory. His original discoveries in hemolytic streptococcus gangrene, postoperative, progressive, bacterial synergistic gangrene and the progressive undermining ulcer and its treatment by the use of zinc peroxide, as well as his discovery of the antibiotic bacitracin, have made him and this laboratory internationally known. He has trained many surgical residents who have organized similar laboratories in other university clinics. Such men and such laboratories make a surgical service wound conscious and jealous of its results in primary wound healing.

HEMOSTASIS

Wounds and the attending loss of blood comprised the primitive surgeon's great problem. These were first treated, in prehistoric times, by pressure, and bandaging with tamponade—measures which were later combined with the use of styptics and astringents. Later the actual cautery and boiling oil methods were employed. This was continued through the centuries until, and after, the time of the French surgeon, Ambroise Paré.

It was probably in the latter period of the Alexandrian School, and not until then, that more definite measures to control and prevent hemorrhage originated. Torsion of vessels and the ligature were undoubtedly in-

vented in the Alexandrian School, for their use was first introduced to Roman surgery by Eulpistus of Alexandria, shortly before the beginning of the Christian Era.

Three great encyclopedists and compilers of the first three centuries, A.D., Celsus, Galen and Oribasius, transmitted Greek and Alexandrian medicine to posterity. It was Celsus who gave the first accurate account of the use of the ligature. He lived in Rome about the beginning of the first century. Whether he was a physician is debatable, but he was an able and scholarly compiler. He wrote an encyclopedia of the arts and sciences of his time, with six sections on medicine and two on surgery. In his discussion, "The Proper Manner of Arresting Hemorrhage," he says.

If there is fear that there may be bleeding one should fill the wound with dry lint, place over it a sponge wrung out of cold water, and press upon it with the hand. If the bleeding still continues, it is advisable to change the stuffing of lint somewhat frequently, and if this step proves ineffective, then lint moistened with vinegar may be tried, for this liquid acts energetically in arresting hemorrhage. Some physicians, indeed, actually pour it into the wound. There is strong objection, however, to the use of an agent, which, like vinegar, arrests the bleeding too completely, for it is apt to set up afterwards an intense inflammation of the parts. The same reasoning applies with even greater force to the employment of corrosives and caustics which produce an eschar. Despite

escaping, and to ligate it in two places, close to the wound, and then divide the vessel between the two ligatures, in order that it may retract (both the new orifices having been already closed by the ligatures). If the circumstances are such that the plan just recommended cannot be carried out, it will then be advisable to apply the red hot cautery to the bleeding vessel.

It is interesting to conjecture why the ligature was used almost as a last resort—probably because the technique of applying it was still in the formative period.

Heliodorus who lived in the Greco-Roman period at the beginning of the second century, A.D., in discussing the operation for hernia, wrote: "We ligature the larger vessels, but as to the smaller ones, we catch them with hooks and twist them many times, thus closing their mouths."

Notwithstanding the knowledge at that time of the use of the ligature, it was not employed for amputations, operations which in those early days were not performed until gangrene had set in, when the incision was made distal to healthy tissue. However,

Heliodorus, in discussing amputations, had this to say. "The hand or foot is amputated if gangrene takes place, or necrosis of an extremity from any other cause. The lower portions of an extremity are removed with less danger, the parts above the ankle or knee with greater risk, on account of the great danger of hemorrhage in most cases, because of the division of large blood vessels."

Galen (130-200 A.D.) advised the ligation of arteries when hemorrhage could not be controlled otherwise and is said to have used it later for amputations. He told where he got his Celtic linen thread for his ligatures—"at a shop on the Via Sacra, between the Temple of Rome and the Forum," a shop near his house on the Via Sacra, by the Temple of Peace.

Paulus Aeginata copies Galen in his treatment of hemorrhage, but adds: "You may know whether it is a vein or an artery that pours forth the blood from this, that the blood of an artery is brighter and thinner and is evacuated by pulsations, whereas that of the vein is blacker and without pulsations."

For the next 1000 years of the Dark and Middle Ages surgery sank to lower and lower levels. Anything which had to do with the shedding of blood was assigned to the barber-surgeons, who had no knowledge of the ligature, and the cautery, caustics and astringent ointments dominated the treatment of hemorrhage.

Lanfranchi of Milan became a political exile, spending most of his professional life in France. He became associated with the French surgeon Jean Pitard in the College de St. Come, which the latter had founded in Paris in 1306. The better educated surgeons of Paris tried to elevate the art of surgery and separated themselves from the barber-surgeons. They wore long robes, whereas the barber forewore robe."

surgery, the *Chirurgia Magna*, and in it discussed the problem of hemorrhage. He distinguished between venous and arterial bleeding and advised the use of a styptic with digital compression for an hour and for severe cases the use of the ligature.

Henri de Mondeville, whom we have discussed in his role as a protagonist of clean wound repair, was a contemporary of Lanfranchi and an advocate of the ligature. He wrote. "Distinguish always between oozing hemorrhage, hemorrhage by jets, and that which pumps out of an inward wound." He

points out the fault of the cautery in stopping bleeding—that when the eschar separates the hemorrhage may recur, and the wound must be disturbed a second time for another application of the cautery. "Let the vessel be isolated from the surrounding parts with the knife, and torsion be used with ligature. Do not, as Galen teaches, allow the wound to bleed with the notion of preventing inflammation; for you will only weaken the patient's vitality, give him two diseases instead of one, and favor secondary hemorrhage. When your dressings have been carefully made, do not interfere with them for some days. Do not pull your dressings about, Nature works better alone."

Guy de Chauliac, who did so much to reject the teachings of Hugo, Theodoric and Henri in primary wound healing, was no more constructive in his dealing with hemostasis, for he still preached the use of styptics and the cautery.

It was not until Ambroise Paré (1510–1590), the most famous of the French surgeons, sometimes, but questionably, called the Father of Modern Surgery, appeared as the great war surgeon of his time that the use of the ligature was restored and the use of the cautery and boiling oil for the control of hemorrhage was discarded. He was at first an apprentice in a barber shop but later came to Paris and served as a dresser in the Hôtel Dieu, a hospital in that city. In 1537 he became an army surgeon and in the many campaigns in which he served he had ample opportunity to study gunshot and other war wounds and wound healing. His modesty is epitomized in his very famous, old French saying, "Je l'ai pansay, Dieu le guerit" (I cared for him, God cured him). He tells of his conversion from the use of the cautery and boiling oil to the more kindly care of wounds:

In the year of our Lord 1536, Francis, the French King, sent a puissant army beyond the Alps. In the conflict there were many wounded on both sides with all sorts of weapons, but chiefly with bullets. I will tell the truth, I was not very expert at that time in matters of Chirurgery, neither was I used to dress wounds made by gunshot. Now I had read in John de Vigo that wounds made by gunshot were venenate or poisoned, and that by reason of the gunpowder; wherefore for their cure it was expedient to burne or cauterize them with oyle of Elders scalding hot, with a little Treacle and . . .

B
auth
cou

paine, I, before I would run a hazard, determined to see whether the Chirurgions, who went with me in the Army, used any other manner of dressings to these

wounds. I observed and saw that all of them used that method of dressing which Vigo prescribes; and that they filled, as full as they could, the wounds made by

It chanced on a time that by the reason of the multitude that were hurt I wanted this oyle. Now because there were some few left to be dressed, I was forced that I might seem to want nothing, and that I might not leave them undressed, I used a digestive Turpen-
troubled
in minde, and the dressing of the precedent day

rose early in the morning, I visited my patients, and beyond expectation, I found such as I had dressed with a digestive only, free from vehemence of paine to have had a good rest, and that their wounds were not inflamed nor tumified; but on the contrary the others that were burnt with the scalding oyle were feverish, tormented with much paine, and the parts about their wounds were swolne.

When I had many times tryed this on divers others I thought this much that neither I nor any others should ever cauterize any wounded with gunshot."

Why tourniquet control of bleeding was not mentioned earlier in the writings of surgeons is very difficult to understand, for pressure was one of the earliest methods mentioned in Egyptian and Greek texts. But apparently the first reference to its use was the introduction of the tourniquet by Morel and of the screw tourniquet by Petit, in 1674 A.D. It was successfully employed in a thigh amputation at the Hôtel Dieu in 1688. Speaking of pressure, Liston, the giant Scot surgeon, is said to have compressed the femoral vessels with his left hand while he amputated the thigh with his right.

Von Esmarch, of Kiel University and a great military surgeon, standardized compression for surgical hemostasis when, in 1873, he devised the multi-fold elastic rubber bandage which has since been called by his name.

There is some uncertainty as to who first invented and used hemostatic forceps or clamps—Eugene Koeberle, an Alsatian surgeon, or Jules Pean, of Paris, in the early 1870's. For many years following their introduction, hemostats were blunt-nosed affairs that crushed more than the blood vessels. It was Halsted who introduced the fine-pointed hemostats that caused so much less trauma

of I

by
Young, 1904.

in the wounds. The use of the Halsted hemostats in the repair of wounds, with Halsted's silk technique, prevents unnecessary immediate, as well as later, bleeding into the wound.

The bleeding tendency, which in the past had been so dreaded by the surgeon, has in recent years been better understood and controlled. Blood transfusion in certain patients having prothrombin deficiency and delayed clotting time has been used effectively. In the deeply jaundiced patient, in whom the bleeding tendency after surgery is so catastrophic, the use of vitamin K for several days before operation has very largely removed this hazard and has made radical operations for the repair of common duct obstruction and for pancreatic tumors possible.

ANESTHESIA

The search for a substance or combination of substances which would relieve the pain of the surgical patient, without danger of

bringing on unconsciousness. Mandragora was described by Pliny, in 70 A.D., in the following words: "It has a soporific power on the faculties of those who drink it. Half a cup is the usual dose. It is drunk against serpents, and before cuttings and puncturings lest they be felt."

During the Middle Ages the sleep-producing sponge—*spongia somnifera*—was used. Hugo of Lucca, the great protagonist of primary wound healing, was quoted by his son, Theodoric, in its elaborate preparation as follows:

Take of opium and the juice of the unripe mulberry, of hyoscyamus, of the juice of the hemlock, of the juice of the leaves of the mandragora, of the juice of the woody ivy, of the juice of the forrest mulberry, of the seeds of lettuce, of the seed of the burdock which has large and round apples, and of the water hemlock, each one ounce. Mix the whole of these

place the same sponge into warm water for an hour, and let it be applied to the nostrils till he who is to be operated upon has fallen asleep, and in this state let the surgery be done. When this is finished, in order to rouse him, place another sponge, dipped in vinegar, frequently to his nose or let the juice of fenigreek be squirted into his nostrils. Presently he awakens

Such an elaborate mixture should have done something to the patient, but the fact

that it fell into disuse was good proof that it was not effective.

Before and after Hugo's time, opium and alcohol were used to produce unconsciousness, but if given in quantities sufficient to produce anesthesia the risk to the patient undergoing crude and shocking surgery, accompanied by great loss of blood, was considered too dangerous by most surgeons.

In the Trustees' Room in the London Hospital, which the writer visited in 1930, there hangs a large bell, similar to the ones on our old steam locomotives. Under it is a plaque, with the following inscription: "This bell formerly hung in the front hall of the hospital. It was sounded to summon the orderlies to control the patients undergoing operation, before the discovery of anesthesia." Left to the imagination was the terror of those about to be operated upon, and the dreadful memories of the patients who had experienced the ordeal.

In "The Diary of a Surgeon in the Year 1751-1752," John Knyveton tells of his experiences as a medical student in one of the hospitals in London. His first introduction to the hospital took place one morning when he went to register in Anatomy. He says:

... The incisions of Doctor Urquehart were placed high upon the thigh. There was considerable pain from the matter the Doctor figure with contentions it is quite common to cauterize them only, with

elapsed before the leg lay on the floor, and much blood was shed. . . . The patient being a poor man had few friends able to make him drunk, and so he being a well developed specimen many ropes were necessary to control his struggles. . . . I wished to enquire what the chances of recovery were, knowing that in such a place they must surely be very small, if indeed existent at all, but after one attempt gave it up as the screams of the porter made speech impossible. . . . The next morning I heard that the porter whose leg was removed yesterday is dead.

It was not until the beginning of the nineteenth century that any real progress was made, and not much of that. In 1800 Sir Humphrey Davy, the distinguished English chemist, experimented on himself with nitrous oxide gas and made the following comment: "As nitrous oxide, in its extensive operation, appears capable of destroying

physical pain, it may probably be used with advantage during surgical operations in which no great effusion of blood takes place." Note the recognition of the hazard of hemorrhage in the state of unconsciousness produced by a noxious drug.

But it was not until 1844 that this suggestion was made use of. Whether it was known to Horace Wells, a dentist in Hartford, is not certain, but in that year he was successful in the use of this gas in extracting teeth. Later in the same year he demonstrated its use, but not successfully, at the Massachusetts General Hospital in Boston. Following the death of one of his dental patients, Wells gave up the use of the gas and, probably brooding over this catastrophe, committed suicide.

The next anesthetic agent to become known as a successful one was ether. This was first described as a chemical agent in 1540, by Valerius Cordus, and was named ether by Frobinus in 1730 in his description of its preparation. It had been used at times to relieve colicky pains and in "ether frolics" by students. But the first surgeon to use it as an anesthetic for an operation was Crawford W. Long, of Danielsville, Georgia. On March 30, 1842, he removed a cystic tumor from the neck of his patient, James Venable, under ether anesthesia. Unfortunately for him and medical history he did not publish a report of this and other cases, but his use of ether as an anesthetic was later verified and vouched for by the doctors in his locality during the controversy that developed over the question of priority. But as Welch said later: "We cannot assign to him any influence upon the historical development of our knowledge of surgical anesthesia, or any share in its introduction to the world at large."

William T. Morton, a dentist and a former partner of Horace Wells, had learned something of the use of nitrous oxide. He later began the study of medicine while still practicing dentistry. One of his instructors was Charles T. Jackson, an able chemist, who taught him the properties of chloric ether. Morton used it in filling a tooth in July of 1844. He then learned from Jackson that sulfuric ether was also an anesthetic and he used it in extracting a deeply rooted bicuspid tooth from one of his dental patients. Later that year he called on Dr. John Collins Warren, of the Massachusetts General Hospital, to persuade him to let him give this sulfuric ether to one of Warren's surgical patients, but did not disclose the name of the new

drug to be used. The operation took place in the historic Ether Amphitheater of the Massachusetts General Hospital on October 16, 1846, on what is called Ether Day. In a few minutes, while the patient was unconscious, Warren removed a vascular tumor located below the jaw on the left side of the neck. As the patient was waking Warren exclaimed, "Gentlemen, this is no humbug." The next day Morton administered the anesthetic for Dr. Hayward, who removed a large lipoma of the shoulder. Henry J. Bigelow, the other Senior Surgeon of the hospital, improved on the method of administering ether and on November 18, 1846, he published the paper in the Boston Medical and Surgical Journal, announcing to the world the successful use of ether as an anesthetic agent, which Weir Mitchell later called "the death of pain."

Morton tried to patent sulfuric ether under the name of "letheon" and did not announce its true nature until 1847. He got into a bitter controversy with his former preceptor, Jackson, over the legal rights of the discovery and later died an embittered and unhappy man.

The high character and reputation of Warren and Bigelow, and the hospital where ether was first publicly demonstrated, accounted in part for the immediate acceptance of sulfuric ether as a general anesthetic. Liston in London used the new drug as an anesthetic in doing a thigh amputation in December, 1846. Syme took it up in Edinburgh in 1847, and the great Russian surgeon, Progovoff, published a manual on etherization the same year. Oliver Wendell Holmes coined the terms "anesthesia" and "anesthetic."

In 1847, the Professor of Obstetrics in Edinburgh, Sir James Y. Simpson, tried ether in his practice, but on November 4 of that year he used chloroform, Liebig's discovery, in delivering a woman and was so impressed with the easier administration of the drug, and the earlier recovery in other patients, that a week later he published his results in a paper entitled, "Account of a New Anesthetic Agent."

Thus, with the discoveries of ether and chloroform and their universal acceptance as effective anesthetic agents, a new era in surgery was born. This was doubly significant, for it not only relieved the patient undergoing operation from the torture of pain and relieved the surgeon inflicting it, but it initiated the era of deliberate and careful surgery on human patients and freed the laboratory workers in experimental physiology and

in the wounds. The use of the Halsted hemostats in the repair of wounds, with Halsted's silk technique, prevents unnecessary immediate, as well as later, bleeding into the wound.

The bleeding tendency, which in the past had been so dreaded by the surgeon, has in recent years been better understood and controlled. Blood transfusion in certain patients having prothrombin deficiency and delayed clotting time has been used effectively. In the deeply jaundiced patient, in whom the bleeding tendency after surgery is so catastrophic, the use of vitamin K for several days before operation has very largely removed this hazard and has made radical operations for the repair of common duct obstruction and for pancreatic tumors possible.

ANESTHESIA

The search for a substance or combination of substances which would relieve the pain of the surgical patient, without danger of killing him, harks back to the earliest days of surgery. Many centuries before the Christian Era the wild Scythians used hemp vapor to bring on unconsciousness. Mandragora was described by Pliny, in 70 A.D., in the following words: "It has a soporific power on the faculties of those who drink it. Half a cup is the usual dose. It is drunk against serpents, and before cuttings and puncturings lest they be felt."

During the Middle Ages the sleep-producing sponge—*spongia somnifera*—was used. Hugo of Lucca, the great protagonist of primary wound healing, was quoted by his son, Theodoric, in its elaborate preparation as follows:

Take of opium and the juice of the unripe mulberry, of hyoscyamus, of the juice of the hemlock, of the juice of the leaves of the mandragora, of the juice of the woody ivy, of the juice of the forrest mulberry, of the seeds of lettuce, of the seed of the burdock which has large and round apples, and of the water hemlock, each one ounce. Mix the whole of these

Such an elaborate mixture should have done something to the patient, but the fact

that it fell into disuse was good proof that it was not effective.

Before and after Hugo's time, opium and alcohol were used to produce unconsciousness, but if given in quantities sufficient to produce anesthesia the risk to the patient undergoing crude and shocking surgery, accompanied by great loss of blood, was considered too dangerous by most surgeons.

In the Trustees' Room in the London Hospital, which the writer visited in 1930, there hangs a large bell, similar to the ones on our old steam locomotives. Under it is a plaque, with the following inscription: "This bell formerly hung in the front hall of the hospital. It was sounded to summon the orderlies to control the patients undergoing operation, before the discovery of anesthesia." Left to the imagination was the terror of those about to be operated upon, and the dreadful memories of the patients who had experienced the ordeal.

In "The Diary of a Surgeon in the Year 1751-1752," John Knyveton tells of his experiences as a medical student in one of the hospitals in London. His first introduction to the hospital took place one morning when he went to register in Anatomy. He says:

Doctor Urquhart was then performing an amputation of the thigh upon a porter, brought in that morning from Covent Garden with a compounded fracture of the left femur, the result of a kick from a horse.

The missions of Doctor Urquhart were placed high upon the thigh. There was considerable trouble from the mass of muscle to find the arteries, which the Doctor for his own advancement wished to ligature with cords, though I learn that in such Institutions it is quite common to cauterize them only, with a hot iron or with boiling tar. Thus from the plunging of the patient, who seemed unable to comprehend that it was done for his own good, and the clumsiness of the Infirmary surgeon, Mr Jamie, ten minutes elapsed before the leg lay on the floor, and much blood was shed. . . . The patient being a poor man had few friends able to make him drunk, and so he being a well developed specimen many ropes were necessary to control his struggles. . . . I wished to enquire what the chances of recovery were, knowing that in such a place they must surely be very small, if indeed existent at all, but after one attempt gave it up as the screams of the porter made speech impossible. . . . The next morning I heard that the porter whose leg was removed yesterday is dead.

It was not until the beginning of the nineteenth century that any real progress was made, and not much of that. In 1800 Sir Humphrey Davy, the distinguished English chemist, experimented on himself with ni-

investigators should be to simplify, rather than to elaborate, the number of drugs and methods of administering them to the patients before, during and after the operation. In recent years there has been a tendency to use too many drugs, in different routes, with the result that cardiac and respiratory complications during and after operation have increased because of the polypharmacy of anesthesia.

TRAINING OF THE SURGEON

The beginnings of surgical training are indefinite and the vagaries, advances and recessions of it are many and involved; but why and when they were involved are closely related to the historical relations of medicine and surgery.

In the hippocratic era of Greek medicine diseases amenable to the simple surgery of that time were few. The physicians trained in the Coan and the Cnidian Schools practiced both medicine and surgery and followed the teachings of the great master, Hippocrates, and his predecessors, which had evolved from the priests of the aesculapian temples. There was no superiority of physician over surgeon.

Hippocrates gave the first authentic instructions to the surgeons of historical times. He described the best position and the best lighting for the surgeon. In the oath attributed to him, he gave the rules of conduct and ethical behavior that have been the standard for both physician and surgeon ever since his time, and this is sworn to by medical students, as they graduate, all over the world.

This same attitude of mutual respect for medicine and surgery was true in the Alexandrian School, where anatomy and physiology made their first advances, owing to the fact that vivisection was permitted on criminals condemned to death. This same attitude of respect held true in the Greco-Roman period but rapidly deteriorated during the later centuries of the degenerate and disintegrating Roman Empire. Galen practiced both medicine and surgery but gave up his interest in the latter in favor of his polypharmacy. His studies in anatomy and physiology were done on animals and his incorrect observations as applied to the human subject remained authoritative for centuries during the next 1500 years.

During the Greek, the Greco-Roman, the Alexandrian, the Nestorian and the Arabian periods, both medical and surgical training were based essentially on the apprenticeship system. This had certain advantages, in that

the apprentice followed the master in his daily dealing with his patients, learned firsthand by close observation and, if the master was interested in teaching, by instruction. But it was faulty in that the apprentice saw the methods and learned the philosophy of one man only, and apprenticeship made him a copier, devoid of the knowledge of other teachers, and discouraged independent thinking or the spirit of research because of imposed authority. So imbued with tradition and the implicit authority of men like Galen were the doctors of the Middle Ages that only rarely did an original thinker like Hugo, Theodoric and Henri dare to question the didactic teachings of their predecessors.

After Galen and Soranus, both great figures in the Greco-Roman period (the latter was the first contributor to the knowledge of the diseases of women), the long night of the Dark Ages began. Notwithstanding the industry of such Byzantine compilers as Oribasius and Paul of Aegina, whose work did not reach Europe until later, medicine and surgery became separated and both sank into deep desuetude. The disruption of the Roman Empire, the degradation of its morals and morale and the invasion of the wild barbarians of the north resulted in near oblivion of arts and sciences.

The steady spread of Christianity and its final acceptance by Constantine introduced a new attitude toward suffering and disease in the remnants of the Roman Empire. The crime and immorality of the later Romans and the invading northern hordes drove many of the Christians into asceticism and initiated the founding of monastic orders and their monasteries. The belief that disease and deformity were Heaven sent, to be accepted in humility, as well as the worsened polypharmacy of Galen with its plague of nauseating drugs and filthy ingredients which only added to the misery of the sick, led to incantations and prayers for the treatment of the sick and, as medical art grew empty, sorcery, demonology and astrology added to the confusion.

As the monasteries increased, many of them established hostels for the sick and maimed where the religious ministrations of the monks were provided them. As time went on, the monastic orders imposed certain defining regulations on those taking orders—three of them striking in nature: the long woolen cassock, the tonsure and the prohibition of the beard. The latter two required the regular shaving of the monks by the barbers who became attached to the

surgery from the stigma of inflicting pain and cruelty on vivisectioned animals. But so many surgeons of that period had been accustomed to rapid and sleight-of-hand operating that the advantages of deliberate surgery were slow in developing. However, anesthesia opened up tremendous possibilities in exploring new and hitherto inaccessible fields that previously had been considered too hazardous because of the struggles of the patient.

Since the discoveries of ether and chloroform, the evolution of the science of anesthesia has been a progressive refinement in general inhalation, local and conductive infiltration, spinal, intratracheal and, in recent years, intravenous anesthesia, with an increasing number and variety of agents singly and synergistically administered.

The invention of the hypodermic syringe and its use in administering sedatives and in anesthesia are important. Who first invented it is uncertain, but it was first introduced in Europe as a medical instrument by Francis Rynd in 1845, and in America by Fordyce Barker in 1856. Thus, we see that the decade of 1840-1850 was of the greatest significance in the battle against pain.

Nitrous oxide combined with oxygen, to combat cyanosis in inhalation anesthesia, was first employed by Andrews of Chicago in 1868. Its use was revived by Goldman in 1900. Crile popularized it in 1901 by giving a preliminary injection of scopolamine and morphine. He called this method *anoci-association*.

Following the discovery of cocaine by Anrep in 1879 and Koller's use of it in eye surgery in 1884, Halsted developed all its possibilities in nerve block conduction and local infiltration anesthesia during the next two years while he was working in New York City. Later procaine hydrochloride, discovered by Einhorn in 1905, replaced cocaine because of its less toxic effect and its freedom from the danger of addiction if used repeatedly.

Spinal anesthesia was popularized in this country by Matas in 1899 and in France by Tuffier in 1900. Stovaine, which at one time was used for its induction, has been replaced by procaine as a vehicle for the safer form of anesthesia in operations.

Rectal ether anesthesia was first successfully induced by Sutton, at the Roosevelt Hospital in New York in 1903, and refined by Gwathmey in 1913. But this form of general

anesthesia has been discontinued for the more efficient forms of inhalation, spinal and intravenous anesthesia.

The use of other gases for general anesthesia, after the introduction of nitrous oxide, was started by Luckhardt of Chicago, in 1922, with the highly volatile ethylene. This was more recently followed by cyclopropane. But these very volatile gases carry with them the danger of greater explosiveness and should not be used except in operating rooms especially equipped to carry off electric spark.

Intratracheal anesthesia, especially indicated for thoracic and cardiac surgery, has become increasingly useful. It was made possible by the discovery by Meltzer and Auer, in 1909 at the Rockefeller Institute, of intratracheal insufflation of air through a tube passed into the trachea of experimental animals which provided "continuous respiration without respiratory movement." It has also been effectively used in operations in which any amount of blood or mucus in the mouth or throat is liable to be aspirated.

Intravenous anesthesia, induced by a variety of drugs, is the most recent development in the field of general anesthesia. Pentothal sodium is the drug most frequently used. The rapid loss of consciousness within a few seconds after the intravenous injection (usually into the median basilic vein) and the quick recovery without nausea and confusion are boons to the patient, who can be put to sleep and will awaken in his own bed and room.

One of the greatest advances in anesthesia in recent years has been the development of the residency training program in anesthesiology. Physicians trained in medicine and physiology entering this field of medical science are given intensive training in the administration of all forms of anesthetics and at the end of three years are qualified to take the examinations of the American Board of Anesthesiology. Thus, qualified physician anesthesiologists are rapidly replacing the less experienced nurses and interns who in the past had given the anesthetics in our hospitals. The many forms of anesthesia, with the many kinds of modalities used to produce them, require a knowledge of medicine and physiology for the greater safety of the patient.

Furthermore, this training stimulates those who have had it to go into the research side of anesthesiology, with the result that new vehicles and new methods of administration are increasing. One of the efforts of these

primary union. Among these were Hugo, Theodoric and Henri.

In 1260 Jean Petard founded the College de Saint Come in Paris for the purpose of distinguishing the lay surgeons, wearing long robes, from the short-robed barber-surgeons, illiterate in Latin. The fact that the lay surgeons were permitted to marry as compared to the long-robed physicians, who were clerics, was an asset, but more important was the fact that the famous French surgeon, Lanfranchi, was the leading light in the college at the time. Increased entrance requirements, including two years of the study of medicine and philosophy in Latin, were followed by two years of surgery before becoming a lay surgeon of the long robe, with the title of *Maitre Chirurgien Juré*.

However, the persistent opposition of the physicians and the failure of the College to recognize Ambroise Paré lost them the leadership of French surgery. Furthermore, they still advocated the use of the cautery and suppuration for they followed the teachings of Guy de Chauliac. The surgical teaching was by apprenticeship under the dialectic teachers of the College. It was replaced in 1723 by the *Academie Chirurgique de Paris*.

Renaissance Surgery. Freedom of thought and the escape from dialectic authority came to Europe in the fifteenth century as the result of several factors: the navigational exploits and the discovery of the Americas; the fall of Constantinople, with the escape of Byzantine scholars with their Greek and Arabic manuscripts into Sicily and Italy; the invention of gunpowder; and, most important of all, the invention of printing, which made possible in great amount at a rapid rate the reproduction of the texts of ancient and contemporary scholars.

In the influence of freedom of thought on surgery, the greatest factor was the introduction of dissection in Padua, Bologna and Florence. Equally significant was the effect on the artists' portrayal of the human form, which resulted in the transition from the primitive to the normal painting of the figure. An interesting story is told of the common meeting ground of the physicians and the artists in an apothecary shop in Florence, where the former came to have their prescriptions filled, the latter to buy their pigments. When it became known that the physicians were having dissections, their artist friends were given permission to observe the dissections, at times crowding out the doctors around the dissecting table.

Undoubtedly Leonardo da Vinci, the first great anatomist of the period, who was then living in Florence, was one of the first artists to join the doctors in the dissections. He is said to have made 750 anatomic sketches from the dissecting table. He may justly be called the father of modern anatomy, although Vesalius, fifty years later, in his epoch-making *Fabrica* had a far greater influence on surgery because of Leonardo's failure to publish his anatomic studies, many of which were not discovered until they were found in the Royal Library in Windsor Castle in 1784.

Vesalius with his *Fabrica* had a profound influence on surgery, as did Harvey with his *De Motu Cordis*, published in 1628, describing the circulation of the blood. For these two great works freed the surgeons from the ban of galenic doctrines which had misled them for centuries. Increased knowledge of anatomy and recurrent wars on the continent and in England, with the introduction of gunpowder resulting in a particular type of wound, increased the standing of the surgeons and the demand for their services. This was especially illustrated in the career of Ambroise Paré, the great military surgeon of the sixteenth century, which has been described.

During the sixteenth and the seventeenth centuries the training of the surgeon in the hospitals and in the armies continued to be by the apprentice method. The lack of anesthesia and asepsis favored speed as the *sine qua non* for the benefit of both patient and surgeon. Little elective surgery was done. Such procedures as herniotomy and lithotomy were still delegated to a few specialists, who kept their techniques secret as well as their whereabouts after they had operated (hence their name "fugitive surgeons"). These so-called specialists had too high a mortality to have permanent offices. Most of the surgery done by the regular surgeons in the hospitals of Europe and Great Britain was of an emergency and traumatic nature. Compound fractures demanded amputation of the limbs involved and even Lister, before he developed his antiseptic techniques, had a 45 per cent mortality in his amputations.

An increasing knowledge of anatomy and the recognition of its importance in surgical training resulted in the surgeon teaching the subject. All the great surgeons of the continent and Great Britain during the eighteenth and the early part of the nineteenth centuries had preceded their work in surgery as

monasteries. A later edict requiring the bloodletting of every monk five times a year increased the work of the barbers and their association with blood.

This all inevitably led to the transfer of any surgical procedure to the barbers, who later came to be known as barber-surgeons. To add to the divorce of medicine from surgery and to the insistence that therapy for any illness not requiring surgery be limited to long-robed cleric physicians, came the famous, infamous Papal Edict of the Council of Tours in 1163, which read "Ecclesia abhorret a sanguine" (the Church shuns blood) Thus was medicine cut off from its more effective and definite form of therapy, surgery, which separation lasted until the nineteenth century. In England to this day the physician is called Doctor, the surgeon, Mister.

Meanwhile, how did Greek medicine and philosophy survive to be reintroduced and rejuvenated into Italy and Europe through the medium of Arabic manuscripts? During the fourth century a small Christian sect in Mesopotamia, known as the Nestorians, became involved in religious controversy. In their desire to get at authentic Biblical sources, they turned to the Greek Septuagint version of the Bible. In doing so the Nestorian scholars became conversant with the Greek language and thus became acquainted with the manuscripts of Greek medicine and philosophy in the Alexandrian School and translated them into their own Syriac language. This led to their establishing a school and hospital in their city of Edessa. With the decline of the school in Alexandria the Greek sources of medicine and science remained with the Nestorians.

Because of the heresy of the Nestorians in their tenet that the Virgin Mary was the Mother of Christ but not the Mother of God, they were expelled from Edessa by the Catholic Church in 489 A.D. and were given asylum in Gondisapor, a Sassanian town in southwestern Persia. Here they re-established their medical school and hospital. They translated their Syriac texts of Greek medicine and philosophy into Arabic and for the next 200 years were the repository of Hippocratic and Galenic medicine. The nascent Arabs, after conquering the Near and Middle East, sought the services of the Nestorian School and Hospital and were tolerant of these Christians because of their views of the Virgin Mary not being the Mother of God.

The Nestorian scholars with their trans-

lations of Greek manuscripts into Arabic assisted the Arabs in establishing medical schools and hospitals in Baghdad, Damascus and Cairo. The Mohammedan conquerors of North Africa and Spain carried Arabic medicine with them, and in Cordova in Spain they established a medical school which did not delegate surgery to menial barbers but produced Arabic and Jewish physicians who practiced surgery as well as medicine. Both medicine and surgery in the Nestorian, Arabic and Cordovan schools were taught by the apprenticeship method, and in certain of the well-organized hospitals bedside teaching was conducted, especially in the Nestorian hospital in Gondisapor.

Until the eleventh century monastic medicine, as practiced by the monks and clerics, consisted in the cult of faith healing, an implicit belief in the miraculous power of the saints and their holy relics. Supernatural help came to be accepted because of the failure of medical art in sickness, especially in the great epidemics. In the eleventh century was established the first independent medical school in Italy, in the town of Salerno near Naples. Monastic, Jewish, Arabic and Greek influences led to the tradition that the school was founded by the Four Masters. To the Salernitan center came the Carthaginian scholar, Constantinus Africanus. He had learned Arabic and had traveled extensively. In Salerno and in the cloisters of Monte Casino he translated into Latin, from Arabic texts, works of Hippocrates and Galen and the Cordovan physicians. In this way Arabic medical doctrine was introduced into Italy and France and profoundly influenced medical teaching in these countries as late as the seventeenth century. It did great harm to surgery in the advocacy of the cautery and of laudable pus in the treatment of wounds.

The establishment of universities began in the twelfth century—Paris (1100), Bologna (1158), Oxford (1167) and Padua (1222), followed by many others. But at first these institutions were under the direction and influence of the Church and therefore the medical students were under servile obedience to dogmatic authority and were forbidden to give any treatment with the hands. The fundamental error of medieval medicine was in its divorce of medicine from surgery.

In the following century, however, a few independent spirits appeared as physicians who did not hesitate to question authority, inveighed against the suppurative treatment of wounds and preached the doctrine of

Hunter was forever observing and experimenting. He commanded his pupil, Jenner, of vaccination fame, who was about to make a journey to the Near East, to bring him a fetus of the camel in each of the eleven months of gestation. It is not recorded by what means he secured the intact skeleton of the famous Irish giant. He became the greatest teacher in anatomy and surgery and had many famous surgeons among his pupils from Great Britain, Europe and America. England became the surgical center of the world in 1800 because of the great surgeons who had trained under John Hunter. Among them were Abernathy, Cline, Astley Cooper, Physic and the physician, Jenner.

Astley Cooper succeeded Hunter and Abernathy as the leading surgeon in London in ability and practice. He contributed soundly to anatomy and surgery. In 1804 he published a beautifully illustrated monograph on hernia. In this monumental treatise he described every known type of hernia, except one, that now is so common, the postoperative ventral incisional variety.

In Scotland the most famous teachers of anatomy and surgery in the pre-listerian era were Robert Liston (1799-1847), William Fergusson (1808-1877) and James Syme (1799-1870), all three of Edinburgh. Liston was a giant physically and was the boldest and most rapid operator of his day. He was one of the first surgeons to use ether anesthesia, but only in the last year of his life. Fergusson was a great anatomist and surgeon. His dissections were superb and the surgical instruments he devised are still in use today. Syme began his work in anatomy and later became Surgeon to the Royal Infirmary in Edinburgh, where he trained Lister and gave him every opportunity to carry on his researches in inflammation.

The lecture system was the accepted method of surgical teaching. The lectures were given, as has been stated, by leading surgeons in the lecture halls of hospitals. But the instruction in anatomy in both England and Scotland at this time was given in private schools of anatomy. The failure of city authorities to permit the dissection of unclaimed bodies of inmates of hospitals and asylums resulted in grave robbery to provide cadavers for the schools of anatomy. Rival teams of grave robbers, called Resurrectionists, vied with each other to supply dissecting material for the surgeons teaching anatomy. Indeed, some of the medical

students attending the anatomy classes engaged in the hazardous business.

In the "Diary of a Surgeon in the Year 1751-1752," John Knyveton, a medical student in Dr. Urquhart's School of Anatomy, had this to say about his part in body snatching:

Nov. 7. Vastly tired this morning as the result of a Hazardous Escapade from which I count myself lucky to have escaped without Grievous Harm to Life and Limb. Mr. Bloomfield did yester eve put to me that we should disinter the body of the hanged woman for the Advancement of Our Art and the Glory of Medicine, and so after some talk I agreed and we approached our worthy teacher who warning us of the Dangers—for hanging is not the least penalty, one is likely to be torn to pieces by the mob should they learn of it—did then commend our Diligence and whilst saying that he would have no hand in it and would know nothing of it should it come to light, did call his huge manservant to him and gave instructions that he was to help us. So home to an early supper . . . and so to Dr. Urquhart's to enter it by the small gate to find that the Doctor had gone out but his man and Mr. Bloomfield and Messrs. Pope and Sinclair gathered in the Anatomy room very comfortable before a fire smoking and discussing a flask of wine. So with them to pass the evening in pleasant discourse. I growing somewhat drunk on the wine, very potent, and when the clocks had struck the half after twelve to collect spades and grapples and to muffle ourselves in thick cloaks. . . . And so into the lane and to the graveyard where Mr. Pope did Belch so loud this causing Dr. Urquhart's man to swear vilely vowing that he would rather have a School of Apes to help him than such turnip heads. The grave not easy to find there being very many in a small place and the moon did come out from behind the clouds which I did not care for as we were more likely to be seen but with its aid to find where the mould had been newly turned. George Blumenfield very vehement to dig up the coffin only to find this being opened did prove to contain an old woman very foul. Then Mr. Sinclair on sitting down did find the ground gave way beneath him and so we found the hanged wench and dragged her out and put in the sack which Mr. Pope and I did then carry between us and with great haste to the lane and so to the Doctors again, all mired and sweaty. George Bloomenfield did brew us a bowl of punch and we in need of such a Specific. Lord, what a business this be, this Quickening of the Awful Dead, at night when the powers of evil be abroad, amongst the tombs and the earth and the dreadful worms! Fit work only for men of British Minds! Did resolve then to have no more of it, but on reflection realize that nothing is gained without labor and so as Medicine be the most noble of the Arts so the Gateway to it is correspondingly difficult and arduous to pass. Slept on a couch at the Doctors, and to home this morning at Mr. Hunt's and with him and Mrs. Hunt to church, where I heard a tolerable sermon aptly enough on the Resurrection, and wonder what his Reverence would say of my night's activities. Shall to bed early this night.

In Edinburgh, in 1827, the town went mad

teachers of anatomy and many of them continued to go from the dissecting room to their operations in the hospital without change of clothes or cleansing of their hands.

France. In France the Revolution played an important role—at first very detrimental, for all the medical faculties were abolished because of their royal affiliations. But the wars in Europe which followed made surgical training mandatory and the National Convention established what were essentially military medical schools in Paris, Montpellier and Strasbourg. Napoleon later organized the Paris School of Medicine and in 1806 he incorporated the medical school into the University of Paris as the medical branch of the institution. When medical education was again reorganized in 1830, there was started the system of the *Concours* by which the candidates for medical and surgical appointments competed against each other by taking oral examinations before elected examining bodies.

During the first half of the nineteenth century, surgeons appeared in France famous for their knowledge of anatomy and their surgical skill. Special mention should be made of Larey (1760–1842), the leading military surgeon under Napoleon, one of his accomplishments being the organization of the famous ambulances to rescue and treat wounded soldiers, of Dupuytren (1778–1835), who became the Head of the Department of Anatomy in the Paris Academy of Medicine at the age of twenty-three and Surgeon-in-Chief at the Hôtel Dieu when he was thirty-eight. Although hated by all his colleagues because of his haughty bearing and disdain for the work of other surgeons, he was acknowledged the greatest surgeon of his day. Lembert, Dupuytren's pupil, devised the intestinal suture which insured the outer approximation of serosa to serosa, and laid the foundation for all modern gastric and intestinal surgery. Velpéau, Malgaigne and Nelaton should also be included among the prominent surgeons of this period.

Great Britain. In the early part of the eighteenth century little, if any, systematized instruction in surgery was to be found. Apprenticeship with a practicing surgeon was the only available method. At St. Thomas' Hospital in London, William Cheselden (1688–1752), then the leading surgeon in that city, began lecturing in anatomy and surgery, and in 1763 Percival Pott (1714–1788) began a series of lectures in surgery at St. Bartholomew's. In 1769 the Medical

School of Guy's Hospital was started and soon after united with the school in St. Thomas' Hospital. Surgical lectures were given there and medical lectures at Guy's Hospital.

In Scotland a medical school was organized in Edinburgh by John Munro. His son, Alexander Munro (1697–1767), started the famous School of Anatomy in Edinburgh. He was succeeded by his son and grandson, so that this Chair of Anatomy was held by the Munros for 140 years.

The most famous of British surgeons of this period was John Hunter (1728–1793), the founder of experimental surgery and experimental pathology, who ranks with Paré and Lister as one of the three most influential surgeons of all time. He was a man of unbounded energy, insatiable curiosity and a determination to know the why and the how of surgical lesions as well as natural phenomena. As an uncouth youth he was brought to London from his home in Scotland by his older brother, William, then famous for his School of Anatomy in Windmill Street. John became fascinated with the study of anatomy which later culminated in the Hunterian Museum of some 13,000 biologic specimens, most of them prepared by him and many of them still to be seen in the Royal College of Surgeons in London.

John Hunter studied surgery with Cheselden and Pott, and later was appointed Surgeon to St. George's Hospital. He developed surgical pathology into a live and essential discipline. His studies of inflammation, shock, syphilis and teeth were unique. But his most outstanding contribution was in the pathology and treatment of aneurysm. From an experiment which he performed by tying the external carotid artery of a deer, he found that the growing antler on the side of the ligated artery, which at first had turned cold, later regained its warmth and continued to grow. When he autopsied the buck he found the ligature secure but saw that the blood supply to the antler was by way of small collateral arteries. "Oho," he said in his notes, "I see that under the stimulus of necessity the smaller arterial channels greatly increase in size to do the work of the larger. I must remember that." This he did, for he changed the old Greek Antyllus operation of ligating the artery above and below the aneurysm to the technique of ligating the artery well above the aneurysm and by-passing the sac, with the development of compensatory collateral vessels.

only survived, but lived to be seventy-eight without any recurrence of her trouble.

During the next hundred years, especially after the discovery of anesthesia, elective surgery increased. Attention was concentrated on the development of new techniques and new instruments. In the late 1870's and early 1880's, the treatment of abdominal acute infections was initiated by the attack on appendiceal abscess—then called perityphlitis. Surgery of the gallbladder, the stomach and the intestinal tract was beginning. The radical attack on cancer was initiated by the radical mastectomy of Halsted and Willy Meyer in 1882; Billroth, in Berlin, performed the first partial gastrectomy for cancer in 1883.

In the medical schools of Harvard University, Columbia University and the University of Pennsylvania, medicine and surgery were taught by the lecture system and little bedside teaching was given before 1890. In some of the schools, private quizzes to prepare men for the competitive hospital examinations were attended far more regularly than the lectures in the medical schools.

Much of the surgical teaching during the latter part of the last and the early part of the present century was given from the operating amphitheater, where the student saw backs and blood but got little worth-while instruction. This led to showmanship on the part of the leading surgeons and a tendency to continue the emphasis on speed in operating, which, of course, appealed to the immature and uncritical students. At this time there began a shift from the emphasis on anatomy to the study of surgical pathology in preparation for surgery. This was to be followed in the early years of the present century by the emphasis on physiology as the most important of these three disciplines as the approach to original and constructive surgery.

In or about 1880, listerism as well as the use of anesthesia had so increased the elective surgery in the hospitals of the United States that internship in surgery became well established. Before this time interns served for both medicine and surgery. The surgical internships were from twelve to sixteen months in most hospitals, with a period of four to six months of houseship, during which time the intern was given operative work, the amount depending upon the good will of the attending surgeons with whom he had been working. In the larger centers like New York City, the competition for appointment to the surgical services was

determined largely by the amount of operative work that was given to the house surgeon. This resulted in a vicious circle, for the hospitals desiring the best men from the medical schools gave an increasing amount of operative work to the relatively inexperienced intern, who, when he left the hospital, went into general practice, doing little if any surgery thereafter unless he later became attached to a surgical service in one of the hospitals.

The change from this short-term and wasteful surgical training to the long-term and sound residency training was initiated by William S. Halsted. He had studied in the best German clinics before he returned to New York City, where for a period of four years he was known as a brilliant young surgeon, imbued with the newer aseptic techniques. A most unfortunate, but entirely innocent, experience with the study of cocaine as an agent for producing local and nerve block anesthesia resulted in his having to drop out of surgery for a period of four years. But this enforced withdrawal from surgical activity gave him time for contemplation and a reappraisal of his ideas of surgical techniques and of surgical training. William H. Welch, his great friend who rescued him from his innocently acquired addiction and who appreciated his great promise as a surgeon, took him to Baltimore to be his co-worker in the newly organized Johns Hopkins Medical School. Welch had been the pathologist at the Bellevue Hospital in New York before he was chosen to be dean of the new school in Baltimore.

Halsted had seen and appreciated the advantages of the long-term training in the German clinics but also was aware of their failure to give this training to more qualified young surgeons. When he was chosen to take charge of the surgical service at Johns Hopkins in 1889, he appointed residents from qualified surgical interns, who served from four to six years, with the appointment to the chief residency for a period of one or more years. This resulted in such well-trained surgeons, after such wide experience in operative and experimental surgery, that his residents were appointed to chairs of surgery in the medical schools of the country.

However, for many years the Halsted residency program was not favorably received in the surgical clinics of the country because of the antagonism of the younger attendings and the surgical interns, who feared that the residency system would deprive them of the operative experience which they had

over the discovery that two of the grave robbers supplying Dr. Knox's School of Anatomy had murdered a number of people by smothering them and had sold them as freshly exhumed bodies to the School. In London, in 1831, two grave robbers were arrested. It developed that they had murdered thirty to sixty people by giving them rum and laudanum and had sold their bodies for dissection. Both were convicted and publicly hanged. Parliament then passed a bill regulating the supply of unclaimed bodies "for purposes of anatomizing." Grave robbery thus came to an end.

During this period of the Resurrectionists the surgeons and the medical students came from the dissecting rooms to the hospitals to take part in the operations and deliveries. Antiseptic precautions were unknown and the varying states of putrefaction of the cadavers, together with the failure to change clothes and wash hands, made hospital infections an unbelievable nightmare. In some of these institutions the mortality reached 80 per cent of the surgical and obstetrical admissions.

Germany. The best known surgeons in Germany during this period were Conrad Langenbeck (1776-1851), von Graefe (1787-1840), Dieffenbach (1792-1847), Stromeyer (1804-1875) and Bernhard von Langenbeck (1810-1887). The elder Langenbeck was Professor of Anatomy and Surgery at Gottingen and Surgeon General of the Hanoverian Army. He belonged to the sleight-of-hand type of surgeon and is said to have amputated a shoulder while a colleague present was taking a pinch of snuff! Von Graefe was the Professor of Surgery at the University of Berlin and is considered the founder of modern plastic surgery. Dieffenbach succeeded von Graefe. He was the first to cut the eye muscles for strabismus and was one of the first to operate on vesicovaginal fistula. He was a cultured scholar as well as an able surgeon and teacher.

Stromeyer was one of the founders of orthopedic surgery and was considered the father of military surgery in Germany. He was a poet as well as a great surgeon. Bernhard von Langenbeck, the nephew of Conrad, became the greatest surgeon and clinical teacher of this period in Germany. Under his tutelage the most famous surgeons of the past fifty years in Germany appeared. Two of his greatest accomplishments were the founding of the German Society of Surgery

and the editing of the great surgical journal of that day, the *Langenbeck Archiv*.

Long-term training in surgery was started in Germany in a pattern of its own, and is continued to the present in much the same form. All students on graduating from the medical school are required to take a year of internship, most of them preferring the rotating type. After that they can become assistants in surgical clinics or, as at present, they may wait out a year as volunteers. This volunteer system is necessary in Germany at the present time because of the great demand and the relatively small supply of such positions. This assistantship is somewhat comparable to the assistant residency in the United States. The assistant can advance to the position of first assistant in four or five years, but few reach this promotion. After this, the first assistant may be promoted to become an *Oberarzt*, comparable to the chief resident in our clinics. But unlike him he may serve in that capacity for a period of ten to fifteen years, waiting for an appointment as the head of one of the surgical clinics. In the meantime, he assists the professor who as the *Gcheimrat* is the omniscient one, not to be questioned in any way, and who does practically all the operating.

The same method of surgical training is followed in most of the European clinics as in Germany, with individual modifications in each country.

America. Surgical training in the United States, until the latter part of the nineteenth century, was by apprenticeship. A few of the ambitious young surgeons of the period under discussion went to Paris, London and Edinburgh for further training. Especially notable were Physic and Dorsey of Philadelphia who studied under John Hunter in London, and Valentine Mott of New York who worked with Astley Cooper and later became famous for his original work in vascular surgery. Ephraim McDowell of Danville, Kentucky, studied under John Bell in Edinburgh. In 1809, he performed the first ovariectomy in abdominal surgery on a forty-seven-year old woman, who had come to his office on horseback, a distance of 21 miles. At the end of the ride she had developed a decubitus of the lower abdomen as a result of the pressure of the pommel of the saddle. McDowell operated while a group of the citizens of Danville waited with loaded guns to operate on him if the woman did not survive the ordeal. The woman not

agers, and now the public, that surgery should be done by properly trained and experienced men. This has made a great difference in the caliber of the surgeons appointed to hospital staffs throughout the country.

It will be recalled that the divorce of medicine and surgery in the Middle Ages resulted in chaos to both. In the present era, although practiced by different groups, the two are so closely related that they cannot be separated as in the past. In our medical schools the etiology, pathology and diagnosis of disease are studied by all the students, as well as the indications for the proper therapy. Many of these diseases require medical therapy in some stages of their development, surgery in others.

The close association of the medical and surgical services in our hospitals today, and the fact that many of the interns in these hospitals serve on both services, break down any of the old barriers between these two disciplines. In many of the courses on the so-called middle ground diseases, teachers from both departments take part, and the teamwork of both groups in the combined clinics on many of these syndromes, and in the follow-up of them, makes the physicians and the surgeons speak the same language, and there are no miracles among friends.

It is now an accepted fact that internal medicine and surgery are but two branches of therapy in the science of medicine.

been having in the hospitals where the short-term training had prevailed. It was not until the 1920's, when the necessity for long-term training became mandatory, because of the advantages to the patients and to the attending staff in the surgical clinics, that residencies were started and soon became the recognized and sound method of training those who wished to prepare for major and radical surgery.

Another change in the policy of surgical teaching in the undergraduate curriculum in the medical schools was the recognition of the fact that training in the operative techniques is a graduate function that has to be done in the hospitals in the surgical internship and residency periods. Teaching the symptoms and signs of lesions requiring surgery was emphasized rather than the techniques of treating them and replaced the lectures which formerly were given in the courses in the surgical specialties. With the crowded curriculum in the medical schools this was essential and sound.

This establishment of residency training in the university surgical clinics in the United States may be justly considered the greatest advance in surgical training in the history of surgery. For as it is now done in these, and the best municipal hospitals of the country, the residents are given the finest operative training and in their last year independent operative work. They are given increasing responsibility, as they advance in their residencies, for the conduct of the surgical services. *This makes them far more experienced in assisting the attending surgeons as well as in the care of the patients, for they live in the hospital and are on call at all times to prevent complications or to treat them promptly if they should occur.* Under this system patients get far more intelligent and constant care than was the case in the old days. Furthermore, under this plan far more surgeons receive adequate training and experience than is the case in European clinics and they are given the opportunity of independent thinking without the domination and dictation of the omniscient *Geheimrat*.

So able and proficient did this young generation of long-term trained residents become, that it became obvious to the leading surgeons of the country that these surgeons should be given recognition. Previously, qualifying boards in other specialties had been organized under the American Medical Association. In 1937, at the instigation of the American Surgical Association, the Quali-

fying Board in General Surgery was organized and began giving written and oral examinations to surgeons who had completed their long-term residency training. If these surgeons passed the examinations, they were given certificates of proficiency, with the understanding that they would limit their work to general surgery.

So outstanding was the ability of these qualified surgeons during World War II, as compared to the work of the medical officers with short-term intern training, that the young officers who had had only nine months of internship were convinced that residency training was essential for any man going into surgery. This conviction was strengthened when the Veterans Administration, properly reorganized after the war, required such residency training for appointment to the position of attending surgeon in the Veterans Hospitals.

Other developments in the surgical field in this country have added greatly to the education and training of the surgeon. The surgical journals that have been published have become increasingly competent in publishing the original studies of the surgeons and in eliminating much of the useless, repetitious and uncritical compilation of clinical material which in the past filled the pages of the journals.

The annual and semiannual meetings of the national surgical associations and small travel clubs provide the very valuable means for our surgeons to see and to hear reports of the work of leading surgical authorities. This is especially true of the meetings of the Congress of the American College of Surgeons, with the presentation of papers and the panel discussions as well as exhibits of laboratory and technical procedures. This is also true of the Surgical Section Meetings of the Annual Meetings of the American Medical Association. Examples of how effective surgical journals and meetings have been may be cited in the astonishing advances which have been made in the field of thoracic and cardiovascular surgery and the spread of the information regarding the techniques of these procedures throughout the clinics of this country. Within a period of two or three years the new methods have come into use in all the leading surgical clinics.

One of the most important results of the residency training program, together with the qualification of the residents who pass the examinations of the qualifying board, is the recognition by hospital boards of man-

hemorrhage, retroperitoneal bleeding from multiple fractures; damage to great vessels; contusions of the heart and lungs, or injuries to the cerebrum and cord.

Delays in diagnosis and treatment may lead to disaster. The newspapers' term, "death from internal injuries," carries with it an air of helpless, or hopeless, mystery which draws from the reader an expression of forgiveness. When the victim of an accident reaches the emergency room, it is regrettable and shameful if every effort, including surgical exploration, is not made to determine the nature and extent of his injuries.

Before considering the local physiologic changes within the wound, one should be familiar with the general physiologic effects of surgical trauma or violence upon the body as a whole, and the significance of the responses resulting from altered endocrine activities stimulated by mechanical, chemical and thermal injuries. These are normal metabolic responses and are usually characterized by a temporary elevation of temperature and pulse rate, a loss of nitrogen from the body for three to seven days followed by positive nitrogen balance, and a loss of potassium for the first two to five days after injury followed by retention of potassium. A transient decrease in the excretion of urine occurs and a diminished urinary excretion of sodium develops for two to five days after injury, following which urinary excretion of sodium increases. A loss of weight occurs. Resumption of caloric and nitrogen intake and a positive balance are requirements important to recovery. A drop in circulating eosinophils and an increase in the excretion of hormone products are the result of an accompanying endocrine readjustment between the pituitary gland and the adrenal cortex.

The histologists and pathologists have provided additional terms to help us in our understanding of wound healing. If a wound is a *break* in the continuity of tissue, *healing* is the *restoration* of continuity of tissue. The factors which bring it about constitute a reaction to injury and the whole process is called *inflammation*.

The process of wound healing may be divided into three phases: *initial or lag phase*, *the phase of fibroplasia* and *the phase of contraction of the scar*.

The use of these terms is not essential to the understanding of wound healing. For example, the *lag phase* was noted from observations made upon experimental ani-

mals in the laboratory. In measuring the strength of a wound following its surgical repair there was, on the first day, a measurable strength provided by the retracted clot which joined the two cut surfaces. The healing process which went on for the next three or four days not only failed to strengthen the wound but caused it to become weaker than on the first day. When the growing strength of wounded tissue is considered, there is a measurable lag which does not start to improve until about the sixth postoperative day. This phase has clinical significance in the management of wounds and it should not be interpreted as one in which the tissues are inactive.

The *phase of fibroplasia* was also determined from laboratory observations. Histopathologic studies showed fibroplasia to begin soon after the injury and to increase rapidly throughout the lag period until it predominated in its own intermediate phase of fibroplasia.

Its occurrence during the lag period is responsible for termination of that phase of healing. The extracellular ground substance which is produced by the fibroblasts becomes converted into collagen which upon contraction begins to terminate the phase of fibroplasia. Again there is considerable overlay in the phases of healing. While fibroplasia alone contributes some strength to the wound beyond that of the original clot retraction, conditions must be right for the chemical changes to convert the extracellular ground substances into the finished product of collagen before satisfactory strength is achieved or maintained.

Preparations for the *phase of contraction* of scar go right along with the entire phase of fibroplasia. Under normal conditions, it accelerates at a rapid pace and starts to become a clinical entity between ten and fourteen days. From then on, scar formation and contraction are the major features of wound healing, continuing for many weeks as the fibroblasts steadily disappear from the scar. The phases of wound healing should not be looked upon as separate acts in a play but as scenes which are taking place almost simultaneously.

The process of healing is initiated by the injury to the tissue cells, and it is essentially the same whether the injury is a planned operative procedure or an accidental wound of violence.

The force causing the injury may create a variety of changes in the tissues, sometimes dividing them as evenly as one could with a

PHYSIOLOGY OF WOUND HEALING

By WILLIAM A. ALTEMEIER, M.D.,
and JEAN M. STEVENSON, M.D

WILLIAM ARTHUR ALTEMEIER, a Cincinnatian by birth, is a product of his home city's educational institutions. He has progressed through the ranks of the department of surgery of the University of Cincinnati College of Medicine to become professor and chairman of the department. He is director of the surgical bacteriologic laboratory and his interests have extended to the detailed study of tissue healing. His contributions to surgical literature have been fundamental.

JEAN MOORHEAD STEVENSON, also an Ohioan, was educated in medicine and trained in surgery at the University of Cincinnati, where he is Associate Professor of Surgery. His interest in the healing of wounds was stimulated by the late Mont Reid.

Wound healing is an inherent physiologic process of animals for the repair of their injured tissues. A knowledge of the mechanism of wound healing and of the local and general factors which affect it is obviously essential. Unfortunately, this process is not the same for all tissues. Highly specialized tissues, such as those of the kidney and brain, repair injuries to themselves by the formation of granulation tissue and ultimate replacement by scar tissue. Less specialized tissues may be regenerated in a form almost identical with their normal structure.

A wound is generally defined as the solution, or break in continuity, of tissue resulting from mechanical force. Mechanical force denotes the characteristic of motion of the object which produces the wound. Thermal, bacterial and chemical agents are also capa-

ble of producing wounds, but the character of the injuries produced and the policies of management and repair are so different that they demand separate consideration.

Wounds may be external or internal, obvious or obscure. Any tissue in the body may be involved in a wound while the skin itself may remain intact. This concept of a wound is frequently overlooked by those who generally consider wounds to be external manifestations of injuries. The student finds it difficult to examine carefully a patient for an explanation of his complaints when there is no evidence of external blood loss or gross distortion of contour resulting from major breaks in the skeleton. He must be on his guard so as not to miss deep injuries such as rupture of the spleen, liver, bladder or kidney, a torn hollow viscus, mesenteric

By phagocytic and enzymatic action, their work precedes the regenerative growth of tissue.

The debris in closed wounds must be carried away by the circulation, while in open wounds much of it may escape to the surface in the form of an exudate or pus. Proteolytic enzymes dissolve dead cells either within or outside of the phagocytic cells. Sometimes bacterial enzymes also assist in this work, but help from bacteria is usually not appreciated because their enzymes may also work on living cells.

Proliferation and migration of endothelial capillary buds into the blood clot begin early and can be seen microscopically on the second day. The fibrin trabeculae in the coagulated blood clot form early and contribute the framework for the subsequent ingrowth of capillaries and fibroblasts from the wound edges. The capillaries supply the nutrition and reserves for the reparative elements and carry away their by-products of metabolism and catabolism.

The early product of fibroblastic and endothelial cell growth is called *granulation tissue* and this tissue is essential to the healing of every wound. There is a tendency to disregard serious consideration of granulation tissue when it lies in a vertical plane between the edges of a sutured wound. The regeneration accounting for this tissue is exactly alike in open and closed wounds, but the very name which was adopted to describe it was the result of observations made in open flat wounds. The same volume of granulation tissue in a closed, or concealed, wound can give rise to future complications.

The fibroblasts secrete and deposit in the granulation tissue a protein, collagen, which produces strength to the bond between the wound's surfaces. The old collagenous connective tissue at the periphery of the wound becomes swollen and fuses with the new collagenous tissue by continuity of cell growth and re-formation of collagen fibrils. The deposition of fibrils begins in the periphery of a wound, which may still contain clot and manifest phagocytic activity, but it does not occur in any portion of a wound containing debris or necrotic tissue.

Clinical signs of the formation of granulation tissue may remain hidden in wounds filled with clot, but one can detect its presence about the fourth or fifth day in flat wounds containing little clot. Steadily, the granulation tissue spreads and thickens until it is no longer possible to recognize the previously exposed tissues, such as muscle, fat or

fascia. The granules which characterize the tissue represent the presence of especially robust capillaries near the surface which sponsor the volcano-like eruption of tufts of fibroblasts and leukocytes.

As a membrane for a surface wound, or as a retaining wall about an inflammatory process, granulation tissue is a great protective device. Although this was known for many generations, it was Billroth who pointed out its protective qualities against bacteria and their toxins in 1865. Billroth demonstrated that signs of tissue destruction, or systemic toxicity, did not occur after the application of contaminants to the granulating surface of wounds when free drainage had been established. The necessity for strict observance of aseptic technique in the management of granulating wounds may be questioned, but the answer is easily found.

Contaminants will grow on granulation tissue and can cause trouble. *Pseudomonas aeruginosa*, usually nonpathogenic for man, has a voracious appetite for newly planted skin grafts. The proteolytic enzymes and other toxins of such bacteria as the hemolytic staphylococcus and the hemolytic streptococcus may be absorbed to produce signs of toxemia. These and other organisms are capable of surviving for years in the cicatrix of a wound which has long been covered by epithelium and may become reactivated by another subsequent injury to the same area. It is wise to remember that some granulating wounds which appear to be innocent may harbor organisms potentially pathogenic for those who dress the wound or for patients near-by with open wounds.

ings
the
granulation tissue and to see the tissue bleed with removal of the dressings. A temporary rise in the temperature curve may follow.

If removal of the dressings is postponed, they may become putrid and the patient may become toxic. Retained moisture and proteolytic enzymes may macerate and even attack the surrounding normal skin. When the by-products of cell growth and bacterial action cannot escape, some of them are absorbed and can produce a systemic response approaching that of an undrained wound.

The wall of granulation tissue about an undrained abscess may keep the process localized. It does not, however, stop the absorption of toxic products from the abscess as long as it is under pressure, as is shown by the febrile response before and after the drainage of any abscess.

sharp scalpel, at other times completely tearing pieces of tissues away from the body or leaving them hanging in shreds along the edges of the wound. A blow may only bruise the skin but mince the deeper fat and muscle or fragment the underlying bone. A glancing blow may do little more than brush away the top layer of skin. When tissues are divided, the contraction of muscle and elastic fibers tends to widen the gap and the continuity of the vascular systems for the blood and lymph is affected. Fluids escape through the breaks into the wound's cavity and to the surface, if a connection exists. The quantity and rate of blood loss is determined by the number, character and sizes of the vessels injured, the nature of the hole in the vessel, the clotting properties of the blood, the types of the tissues injured, the activity of the patient, and the patient's blood pressure.

An effective clotting mechanism is essential to the preservation of life. If bleeding into a wound could be prevented, one would observe that lymph and plasma would fill the wound with clot and serve the processes of healing equally as well as blood. Some of the fluid which collects in a fresh wound comes from lymph and plasma but the material is always colored with red blood cells from damaged vessels or an old blood clot. When the fluid which has collected in closed wounds is aspirated repeatedly with a needle and syringe, it will become progressively clearer until it resembles pure lymph or plasma.

When a wound becomes coated with coagulum, the bleeding stops and further loss of fluid will consist of plasma or lymph whose flow to the surface is essential to the continued growth of the granulation tissue. The coagulum which forms on granulation tissue comes from the clotting of plasma and lymph while the serum becomes a by-product of this reaction.

The formation and retraction of the clot stop the bleeding unless the force of the stream is too great. Completely divided vessels will contract and retract, favoring stoppage with clot. Partially divided vessels cannot retract and the lacerated lumen is held open, prolonging hemorrhage or predisposing to secondary bleeding. Severed capillaries retract and contract just like larger vessels. In experimental studies, they have never been seen to clot, but they may open up and resume function under more favorable conditions.

A clot which retracts poorly is soft and inefficient. Bleeding may recur in such wounds

after displacement of the clot during dressing. A firmly retracted clot efficiently stops bleeding, supports the wound's edges and gives the wound what little strength it has in the early hours or days of healing. This clot also provides better footing for the cellular invasion beginning at the periphery of the wound.

Excessive bleeding and clotting are undesirable and may become hazardous. A large clot cannot move itself and it has little resistance to bacterial action. Its organization delays wound healing, increases the inflammatory reaction and leaves behind an abundance of troublesome scar. In some instances, the clot's center will become liquefied, or infected, before it can be organized and will then require removal by aspiration or incisional drainage. In sutured wounds, large clots may create pressure, favor tissue necrosis, separate wound edges, increase morbidity or impair function.

Another effect of injury is the stimulation of an increased blood flow to the area. The resultant vasodilatation causes the skin to turn pink and produces an increase in local heat. This response is immediate and it continues throughout the healing of the wound.

Immediately after trauma, the pH of the tissues at the site of injury is shifted toward the acid side. In the deeper tissues, a pH of approximately 6.4 will develop and continue during a considerable period of the healing of the wound. This is believed to be one of the factors which produces hyperemia, capillary permeability and local swelling due to an increase of intracellular and extracellular fluids. The swelling which develops is related to the type and severity of the trauma, but all soft tissues do not respond similarly. Rather insignificant injuries about the eyes and lips produce much more swelling than do similar injuries of the trunk or extremities.

Marked swelling delays the process of healing because it restricts circulation, retards local metabolism, produces necrosis of cells and favors bacterial growth. Mild localized swelling, however, is considered to be beneficial. Capillary permeability increases, the channels widen, the rate of flow decreases and the leukocytic cellular elements collect along the capillary walls and make their ways through the walls into the tissues. Leukocytes, histiocytes and macrophages arrive in the injured area to aid in the removal of debris and the defense against bacteria. The phagocytic cells, instead of circulating through the clot, apparently dissolve their way into it by enzymatic action.

ritability. Pain is frequently present and the wound may have a putrid odor.

Unhealthy granulation tissue is prone to occur in wounds which are chronically infected or in old wounds having a densely scarred base in which the period for response to normal healing has passed. Any ischemia resulting from scarring of the base or other causes produces gray, yellowish-pink or cyanotic granulations. They are hard and fixed from fibroblastic growth and the formation of cicatrix. The surrounding tissues are likewise hard and scarred. Pigmentation of the neighboring skin is common. The wound is unusually sensitive owing to nerve regeneration and a lowered *pH* resulting from the stasis. Epithelization and generation of new granulations are at a standstill.

The aging process of granulation tissue is largely the function of the fibroblasts. They produce the homogeneous ectoplasm and fibrils which have attachments to the cell bodies. Their arrangement seems to be affected by the lines of stress and their appearance, in increasing quantities, coincides with the initial and continued shrinkage of the wound. This is not readily detected in the week-old wound, but the development of the collagenous fibrils imparts to the wound a steadily increasing tensile strength for the ensuing several weeks. Because a wound shows no gain in tensile strength until about the sixth day after injury, the term *lag period* is applied to this interval in the healing of a wound. It must be remembered that only because the tissues have been teeming with activity is an increase in tensile strength possible in such a short time. After the sixth day the tensile strength increases rapidly.

The end result of this process of fibroplasia is scar or cicatricial tissue which accounts for the tensile strength, hardening and toughening of the wound as well as for occasional undesirable sequelae.

Scar tissue, however, is seldom as resistant to tension as is normal tissue. When present in excess it may become a point subject to abnormal stretching or herniation. An excessive force may stretch the scar into a state of disruption (Fig. 3).

Whenever possible the surgeon directs the process of healing along lines favoring the minimal amount of scar tissue. The formation and contraction of scar are great aids to the epithelization of an open wound because they reduce the size of the area to be covered by epithelium. The surgeon who is unaware of the part which contraction of scar plays in wound healing will erroneously

Figure 3. Hypertrophic scar. The skin mark on the abdomen was created by an abdominal incision. Tissue tension widened the scar and stimulated a hypertrophic change. The process is regressing as shown by the transverse wrinkles. Abnormal tissue tension produced a hernia for this patient. The fingers mark the edge of the fascial defect.

credit the dramatic change in size during the second and third weeks of healing to epithelial regeneration. This contraction takes place in a concentric manner, but the greatest potential for shrinkage is in its longest axis. Scar will first effect its contraction in a line of least resistance and such areas may be the last to show softening and relaxation. Examples of these are readily found about the eyelids, lips, neck and flexor surface of joints.

Fibroplasia may also cause an increase in tensile strength of the wound and shorten the period of morbidity. Tests on experimental animals have shown that healed sutured wounds of the enteric tract may be stronger than the normal tissue. Specimens inflated with air often burst at a point removed from the site of injury.

Unfortunately, the contraction of scar is a powerful force which can abnormally produce distortions and contractures (Fig. 4). There is little elasticity in scar tissue. If moderate traction is maintained for a long time, contracture can be improved; but when the pull is discontinued, there is a gradual and definite return to the original contracture. Excessive force suddenly exerted upon a scar may disrupt it.

Other effects of scar contracture include a squeezing effect upon all of the elements within the wound. The edema begins to recede. The capillaries become compressed and may be gradually obliterated, resulting in fading of the redness of the wound area. The tissues become stiff and hard. In large deposits of granulation tissue, cicatrization continues over many months, the final conversion of red scars into characteristically white ones may require a year or more.

Although the tensile strength of a wound may be adequate for the resumption of function in two, three or four weeks, depending

Granulation tissue can provide for the patient other kinds of protection, often unnoticed and unappreciated. A coat of fibrin may reduce the sensitivity of the exposed surfaces of a fresh wound. Sensory nerves grow into the granulations, but they do not reach the surface until approximately the second week, and have been manipulated. They have been made to retard the deposit of excess granulations.

Another variety of protection offered by granulation tissue is the preservation of vitality in tissues, such as nerves, tendons, bone, large blood vessels and cartilage. These tissues are easily damaged or killed when continuously exposed to the drying effect of air, repeated dressings or bacterial infection. Preservation of the protective clot, followed by its early organization into granulation tissue, protects such special tissues and permits them to survive.

Much valuable information can be obtained by observing and studying granulation tissues. The use of the word *healthy* or *unhealthy* is more practical than employment of the term *normal* or *abnormal*. Normal granulation tissue need not be the same as healthy granulation tissue. The granulation tissue normally found in a fifteen-year-old leg ulcer would be most unsuitable for the support of a skin graft.

The desired healthy granulation tissue is a thin, firm, bright-red membrane with a finely granular surface which does not bleed easily and which has no offensive odor (Fig. 1).

Figure 1. Healing by secondary intention. Large deep granulating wound of arm covered with healthy granulation tissue

The fluid loss from its surface is minimal and it should resemble a transudate rather than an exudate. No foreign or necrotic material should be present in the wound and the surrounding tissues should show no signs of irritation. The growth of epithelium over its peripheral margins is indicative of a healthy state which will support epithelial growth. Healthy granulation tissue may contain bacteria but will not show signs of acute infection.

Unhealthy granulation tissue, on the other hand, is usually pale or cyanotic and wet and soft from edema (Fig 2). Its friable surface bleeds easily. The surface is coarse and irregular as a result of overgrowth of tissue in some areas and limitation in others. Excessive exudation, or pus, covers the surface, saturates the dressings or irritates the surrounding skin. The patient may show signs of toxicity in the form of fever, edema of the part, regional lymphadenitis, malaise and ir-

Figure 5 The stimulation for tissue growth created by an injury becomes abnormal in some patients. A, Keloid has formed in the margin of a burn which was partially covered with skin grafts B, Keloid formation in donor sites for skin grafts.

The stimulating effects of trauma on scar tissue can readily be observed in many post-operative incisions. Patients leaving the hospital during the second week following their operations will be free of skin sutures and will show smooth, soft, hair-line approximations of their skin incisions. When observed over the succeeding months, many of the incisions will become hard, raised, deep red in color and will stretch from $\frac{1}{4}$ to $\frac{1}{2}$ inch in diameter. These are hyperplastic scars. They will recede in due time unless the patients are "keloid formers" (Fig. 5). This type of hyperplastic scar is commonly found in areas where the skin closure is under tension resulting from loss of skin; stretching from muscular activity, increased tension from heavy fat deposits, and stretching of the abdominal wall from intestinal distention, ascites, tumor or pregnancy. However, such wounds are sufficiently strong to resist total disruption. Prolonged splinting will prevent the overgrowth of scar, but any excess maintained for a long period will stretch the matured scar into an ugly mark. Excessive scar tissue is very susceptible to trauma and small hemorrhages or chronic ulcerations frequently occur beneath, or in the epithelium covering, the scar tissue (Fig. 6).

Thus far, it has been necessary to assume that epithelization of the wound has gone on

protective as a covering of the body surface, resisting bacterial invasion, regulating temperature and preventing loss of blood and lymph. It permits muscular contraction and expansion, remains soft and supple, yet seldom wears out. It absorbs beneficial effects from light but throws down a barrier of pigment in an effort to prevent overdose. To counteract drying and reduce reaction, it will

reach an advanced state of cicatricial formation without epithelial coverage. Epithelial growth is of prime interest since the functions of intact skin are so important. It is

on the location and type of tissue injured, its actual strength continues to increase during the aging of the cicatrix. As the strength of the wound increases, the stimulation for growth of the tissues involved in the repair will be found to decrease. However, repeated injury to a healing wound will prolong the effect of the stimulation for growth. The manner in which this is brought about is not known.

Tissue cultures of fibroblastic tissue show that growth will advance just so far and then come to a halt. It is not cicatrization or circulatory ischemia which stops it because the growing cells at the periphery are bathed in fresh media and could keep right on growing, if so inclined. Obviously, it is not the influence of a completed regeneration of an epithelial coverage. Epithelial cells do not take part in the tissue culture experiments and, furthermore, we know that the healing of concealed wounds behaves the same way with the skin remaining intact. It

is fortunate that tissue growth does slow down as healing advances and that it can stop itself at the right time.

If cultures of fibroblastic tissues are fed until the masses stop growing, and if incisions are made in these masses, growth will start again. Products from the injured cells stimulate the regeneration and this can be repeated on the same tissue culture. The effect becomes less each time, however, and will not go on indefinitely.

A related effect can be observed in clinical wounds. A granulating wound which is too large for spontaneous regeneration of epithelium may be dressed and carefully tended until growth seems to stop. The placement of pieces of skin graft in the wound will be found to stimulate the marginal epithelium to grow again, so that it will have joined the marginal grafts before the grafts themselves have started to send out new epithelium. In this instance, the stimulation must come from the cut epithelium applied as grafts.

diameter. These are hyperplastic scars. They will recede in due time unless the patients are "keloid formers" (Fig. 5). This type of hyperplastic scar is commonly found in areas where the skin closure is under tension resulting from loss of skin; stretching from muscular activity; increased tension from heavy fat deposits, and stretching of the abdominal wall from intestinal distention, ascites, tumor or pregnancy. However, such wounds are sufficiently strong to resist total disruption. Prolonged splinting will prevent the overgrowth of scar, but any excess maintained for a long period will stretch the matured scar into an ugly mark. Excessive scar tissue is very susceptible to trauma and small hemorrhages or chronic ulcerations frequently occur beneath, or in the epithelium covering, the scar tissue (Fig. 6).

Thus far, it has been necessary to assume that epithelization of the wound has gone on to completion. It must be remembered, however, that granulation tissue, starting to mature at the periphery of the wound, can reach an advanced state of cicatricial formation without epithelial coverage. Epithelial growth is of prime interest since the functions of intact skin are so important. It is

protective as a covering of the body surface, resisting bacterial invasion, regulating temperature and preventing loss of blood and lymph. It permits muscular contraction and expansion, remains soft and supple, yet seldom wears out. It absorbs beneficial effects from light but throws down a barrier of pigment in an effort to prevent overdose. To counteract drying and reduce reaction, it will

thelium if the area is not wide. The size has not been established because there are many variables which affect the migration. In dark-skinned people, all depths of the epidermis are pigmented, but the deepest cells are the most heavily pigmented. It is interesting to watch pigmentation develop in the larger, spontaneously healed burns of the Negro. The deep second degree burns which have regenerated spontaneously show a pigmented honeycomb effect. The comb itself is black and represents the deep valleys between the papillae filled with stratum germinativum which survived the burn. The part of the comb intended for honey is red. It represents the epidermis burned through into the corium at the apices of the papillae with recent regeneration of epithelium and no pigment. In due time the pigmentation becomes confluent. If the burn should go a millimeter or two deeper, the pattern is reversed. The red epithelium takes the honeycomb design while the pigmentation becomes spotted. This represents the deepest aspects of the papillae toward the subcutis side with preservation of the merest fragment of stratum germinativum. Such a wound may also become pigmented ultimately throughout.

Following the epithelization of granulating wounds, papillae formation is very poor. Glands and hair follicles do not form, and elastic fibers appear very slowly, if at all. Even then, it may be months or years before they are present in the more favorable locations at the periphery of the wound.

Sensation will return to skin grafts, and to spontaneously epithelized wounds, if the peripheral nerves are intact and if the granulation tissue is not so thick as to be impervious to the growth of nerve fibers. The degree of sensation may be expected to improve up to one or two years after injury.

With the exception of the cellular elements which are carried in the blood, the bulk of the work in the basic processes of wound healing which go on in all types and sizes of wounds is done by the fibroblasts, endothelial and epithelial cells. This holds equally well for injuries to special tissues.

Because of the multitude of variations which may arise as a result of the wound's location, size, shape, duration, causative agent and treatment, some method for sorting and grading wounds in relation to the character of their healing is of practical value. A classification is helpful in the study, evaluation and teaching of wound management. Galen, in the second century A.D., is

given credit for devising the terms of primary and secondary healing and, as the terms continue to be in everyday use, it is necessary to sort out certain features of wound healing and group them according to their applicability to these terms.

PRIMARY HEALING

This type of healing is nearly always described as wound healing at its best. It is healing by *first intention* (Fig. 7). It is the healing of a closed, or concealed, wound without the complication of infection, or the secondary opening of the wound for the release of blood, lymph, serum, body secretion or excretion or foreign body. It will include the ideal wounds as well as those which show edema, discoloration or hardness from excess blood, as some granulation tissue forms in the majority of closed wounds. It is wrong to set up a classification which would preclude this fact. Acceptance of the thought that the majority of the wounds which heal per primam do so through the formation of granulation tissue places no restriction on the effort to approach the ideal of wound healing and gives a category for the wounds not belonging in the class of open wounds.

In some classical examples, scarcely any cellular reaction is described in response to the injury which was made so smoothly that practically no cells were destroyed. The wound is aseptic; the parts are approximated accurately; hemostasis is so perfect that no fluid forms within or leaks from the wound, and scar tissue is minimal or absent after healing.

Figure 7. First intention healing. The thin line on the neck represents the healed incision through which a radical neck dissection was done.

cover itself with oil. Cutaneous epithelium is in a constant state of regeneration, the deeper cells replenishing the supply of new cells to compensate for the constant shedding of old.

After injury, areas of regenerated epithelium will not retain all of these functions. A free graft of skin may carry with it portions of oil glands, sweat glands and hair follicles, but these elements do not form in the new epithelium which grows spontaneously from the margins of the wound or the graft.

Epithelium starts to grow immediately after injury, if it has a place to grow. The closely approximated wound and the abrasion will permit prompt growth. The jagged wound with frayed edges of devitalized skin cannot grow epithelium until the dead tissue is removed. A wound with sharp edges and no approximation will not grow epithelium until the clot beside it is organized into granulation tissue. Epithelium will not grow across fibrin unless there is active circulation immediately beneath it. Epithelium does not grow readily downward into a hole or upward over a hull which is at right angles to its surface. It grows slowly in large wounds and often will stop growing before the contraction of the scar is complete, thus leaving most of the wound uncovered. When granulation tissue is just right for epithelial growth, the rate of coverage is most rapid.

The corium of normal skin is derived from the mesoderm while the epidermis comes from ectoderm. The sweat glands, oil glands and hairs are ectodermal in origin. The real focus of skin regeneration is from stratum germinativum of the epidermis. In working with split thickness grafts of skin, one finds little trouble in getting any thickness of graft to grow, provided the cut surface does not extend deep to the papillae to include a layer of adipose tissue. Free adipose tissue transplants poorly and when left attached to the undersurface of a skin graft, jeopardizes "take" of the graft. A graft taken deeply into the corium will retain good pigment and a sufficient amount of elastic fibers to impart good cosmetic and functional properties to the graft. The preservation of a portion of stratum germinativum of the epidermis is the surest way to obtain epithelial regeneration.

Rather fantastic accounts are given of the capacity of the epithelium to re-establish continuity in brief periods. In these instances, the wounds are minor and perfect appositions of the parts are required. When these conditions are provided, it is sometimes

difficult to tell where the injury had occurred after a period of twenty-four hours. In the strictest sense, such wounds are not actually healed but are held together by their coagulum.

Crusting, or the formation of a scab, in small wounds is Nature's way of simplifying wound care and wound healing. The drying of the wound's seepage creates a tough, elastic film over the unhealed surface. This film sticks to the dry superficial cells of the epidermis so that the epidermis is securely held in place. Additional bacteria rarely get through and if those beneath do not cause a serious infection, the crust will stay on until epithelization is complete and strong. To many surgeons, crusting is regarded as something used by Nature for the healing of non-surgical wounds. This is an error, because in some degree it is found to cover the skin edges of sutured wounds, even those most carefully approximated. It makes possible the early removal of sutures in wounds of cosmetic importance so that scars are not produced by the sutures themselves. The substitution of some variety of cutaneous adhesive dressing will protect the wound from damage by violence.

To a lesser degree, scab formation occurs at the periphery of the larger open wounds beneath which the growth of epithelium may be studied. Tongues or sheets of cells, coming from the stratum germinativum of the epidermis, make their way by enzymatic action through the fibrin under the crust. If mechanical effort is made to remove the crust which is adherent to the epithelium in the early days of healing, some of the fresh epithelium may come away with the crust. Spontaneous separation of the crust will occur in about two weeks.

It is important to have a clear understanding of these principles so that one does not hinder the regeneration of skin by vigorous attempts to cleanse wounds. The use of lubricated dressings on open wounds has come about as a means of protecting the delicate strands of epithelium beneath the peripheral crusts. Any other dressing which would adhere to the crusts cannot be removed without pulling away many of them with their epithelial elements. Dressings designed to be left in place for many days have not been wholly satisfactory because of the retention of the irritating drainage from the granulating wounds. Although crusts never really dry under lubricated dressings, they do stay gummy and remain in place.

Pigmented cells will migrate into new epi-

detached pieces of fat and muscle which, when freed of blood and dirt, can be made to resemble closely the tissues remaining in the wound. Structurally, the living and detached tissues may be the same except for the property of bleeding. However, these detached tissues are devitalized, that is, detached from life. If returned to the wound, it is unlikely that they will survive as grafts. If they fail to live, they lose the color and firmness associated with living tissue. Individually, the cells break down and, as a group, the tissues soften, fall apart and liquefy. The process is one of necrosis and the tissues become necrotic.

The removal of devitalized tissues in fresh wounds, by various techniques of débridement, has become an accepted measure in their operative care. It is customary in some hospitals to regard the surgical treatment of a fresh wound as a "débridement," regardless of the fact that tissue may not have been removed during the operation.

When devitalized tissues of significant quantity are allowed to remain in wounds, they proceed to become necrotic. The number of enzymes, the leukocytic response, the capillary permeability, the fluid loss and the absorption of toxins from the wound are increased.

Dead or devitalized tissues are locally irritant, serve as an excellent pabulum for the growth of bacteria and divert energies of living cells from the problem of repair to the problem of elimination of foreign materials. Foreign body reaction occurring about foreign bodies or dead tissue may delay wound healing and foster infection.

Locally, the swelling, redness and tenderness will exceed expectations. Open wounds will have profuse drainage and the material will be of exudative nature. Both fibrosis and epithelization are delayed. Not until the necrotic tissue is expelled or removed by the mechanical means of excision or dressings will the drainage subside and healing progress.

It is, therefore, important that devitalized or necrotic tissues resulting from injury should be removed by surgical dissection before active bacterial growth and infection have developed. It is also important that the surgical treatment does not result in any unnecessary trauma to the tissues during or after the operation.

Infection. Infection is the greatest enemy of wound healing. The development of any infection, particularly in large wounds, almost certainly increases the period of mor-

bidity after operation since it produces further destruction of tissue and suppresses the process of healing. Tissues destroyed by infection are usually replaced by scar tissue, which may affect function as well as cosmetic appearance.

The surfaces of the human skin and mucous membranes normally are contaminated with bacteria. The microorganisms lie in pits, creases, glands and hair follicles beyond the reach of surface washing. When the body's surface is penetrated by trauma, bacteria cross the cutaneous protective barrier and penetrate the physiologic interior. They may also be carried into a wound by the object producing the trauma or by foreign bodies.

Experience has shown that bacteria may be present in a wound without producing the slightest clinical evidence of infection and that certain factors influence their growth and development. Healthy tissues have a remarkable capacity to kill bacteria or withstand their effects, while unhealthy, irritated or devitalized tissues have limited or little power of resistance to their action. Dead tissue in a wound invites and supports the growth of virulent organisms as well as nonvirulent or saprophytic ones. Therefore, it is extremely important to remove any potential pabulum for bacteria and to prevent the development of a similar breeding ground during the postoperative state.

On the other hand, the apposition of live tissue to live tissue after the thorough removal of all foreign, dead or dying tissue promotes healing even in the face of some contamination. The physical condition of the patient is an important predisposing factor to infection. Dehydration, shock, malnutrition, exhaustion, uncontrolled diabetes and anemia may lower his resistance sufficiently to permit bacterial invasion.

Just as the fibroblasts, angioblasts and neutrophils have enzymes to help them to make their way into fibrin, bacteria have toxins and enzymes to take them through the tissue barriers within the wounds. The powers of materials liberated by injured cells are slight when compared with the potencies of those produced by bacteria. It is little wonder that the surgeons prefer to look upon "inflammation" as the handiwork of bacteria and exclude the reactions of uncomplicated repair.

The staphylococcus produces a coagulase which clots small vessels and favors spread by septic emboli and hastens local gangrene. Some staphylococci and streptococci produce hemolysins which break up red blood

A description like this nearly removes primary healing from the realm of surgery and places it out of reach of practicability. Healing is a reaction, and without any reaction, healing would not occur. To eliminate all hyperemia about a wound is an impossibility. The reaction from a pin scratch or from the injection of a local anesthetic may last for days. The mere preparation of skin with its shaving and scrubbing can reduce it to a state of "weeping" with plasma before the incision is made. Every primary dressing that is changed is stained with wet or dried fluid from the wound. No incision can be made through the skin without leaving some scar. Surgical technique cannot be expected to outdo Nature. The ideal wound has to be coddled just as long as any standard wound, to insure healing without complication.

The reaction is more quantitative than qualitative throughout the steps of repair in primary healing. When the tissues are in accurate apposition and when surgery has effected most of the desirable requirements for good healing in a closed wound, there will be a minimal reaction and less work for the tissues to do. One cannot speed the healing, but one can control the factors which are capable of delaying it.

SECONDARY HEALING

It is probable that the idea for giving this type of healing the title of *healing by second intention* came from the recognition of second attempts at healing by wounds starting out well but breaking down under the effects of suppuration. We still regard the healing of such wounds as secondary (Fig 1). Generally, our minds carry us to the more spectacular examples found in the larger, open wounds created by surgery, disease or accident which were not closed. Open wounds which heal without becoming acutely infected do so by secondary intention. They cannot heal by first intention, unless the surgical attention given them at the time of the injury provided for them a skin coverage by flap graft or free skin graft. In this case, the wounds would no longer be "open" and would then qualify for primary healing, if the skin coverage were to remain intact. The detailed description of the organization, aging of granulation tissue and epithelization is an accurate account for the healing of a wound by second intention. It is not the quantity of the granulation tissue which distinguishes the two, but the absence of epithelial coverage that accounts for secondary healing.

THIRD INTENTION HEALING

An open granulating wound which is assisted in its healing by an operative procedure is changed from healing by *second intention* to healing by *third intention*. Again the implication is that the work was accomplished after a third attempt. This is not always the case, because often no opportunity was given for the wound to heal by first or second intention. It is a little disturbing to be told that a wound upon which a secondary closure has been done actually heals by third intention. If primary and secondary healing include all stages of growth of granulation tissue and epithelial coverage is eventually acquired in both, what new and different process in wound healing takes place in third intention healing?

Third intention healing is a convenient term for surgeons. In the strictest sense, it implies the use of a skin graft, or delayed closure, in the treatment of a granulating wound which is healing satisfactorily by second intention, in an effort to obtain earlier healing, less morbidity and a more functional and cosmetic result.

The physiologic process of wound healing is subject to great variations. Optimum wound healing is the normal rate of wound healing under physiologically normal conditions. Numerous experiments, of Howes and others, have shown that there is no known substance for topical or systemic use which will accelerate the rate of wound healing beyond the normal physiologic rate. The variation in wound healing is one of retardation or limitation caused by a number of factors, both local and systemic.

LOCAL FACTORS IMPAIRING HEALING

Medications which "heal" wounds may be looked upon in the same way that teachers "learn" their pupils. Both assist in the accomplishment of the respective goals, but, just as the pupils do their own learning, tissues do their own healing.

Tissues have their own normal rates for growth in the process of healing. This rate is approached when all of the variables advantageous to the healing rate are present in a normal amount and when all of the variables having the ability to disturb or retard the healing processes are controlled or absent.

Devitalized Tissue and Necrotic Tissue. These terms are not to be used interchangeably. While each is nonliving tissue, necrotic tissue implies greater advancement of tissue degeneration.

In a fresh wound of violence, one may find

which come closest to the ideal are used as foreign bodies intentionally placed in certain wounds to serve a useful purpose. When the reaction is minimal, the tissues tolerate them and encase them in scar tissue.

Many metals not considered desirable for use in surgery are tolerated by tissues which surround them with scar, but a delayed injury from their presence may be suffered. Lead bullets may slowly decompose to produce lead poisoning. Iron may corrode. A fragment lodged in an eyeball may cloud the tissues with pigment and cause blindness. Sharp objects, such as needles, may travel through the tissues from the effects of pressure endured during exercise and introduce complication by their penetrations. Large and irregular objects resting against pressure areas may produce erosion.

Other physical attributes affect tissue tolerance. Porous materials are tolerated less well than the solid and impervious ones. This is especially true when bacteria are growing in the wound. A monofilament suture will do better than one made with twisted or braided fibers. The fewer foreign bodies left in the wound and the smaller their sizes, the better will be the tissue tolerance.

Foreign bodies may be the primary irritants because of their chemical natures. Strong acids and alkalis may effect their own burns and many salts are locally or systemically poisonous. Insoluble foreign bodies such as glass, gravel and carbon particles can be looked upon as inert substances. If not contaminated with bacteria, they may remain in the tissues with little or no reaction if not removed by operation.

Organic materials such as grass, straw, clothing and wood are not tolerated. The usual bacterial contaminations will cause recurrent inflammations until they are removed.

Sutures are also examples of foreign bodies. Catgut sutures are so chemically constituted that human tissues may act upon them and destroy them. Nonabsorbable sutures must be inert and nonirritative to tissues.

Homologous skin will grow but soon apparently produces antibodies in the host which will destroy the grafts about the third week. Homologous grafts of fascia, cartilage and blood vessels are tolerated much better than are grafts of skin elements. The tissues do not live, but their forms are preserved for structures of fixation by the host's cells, provided the grafts are not complicated by infection.

When a foreign body lies in badly damaged tissues, its chances of retention within the wound are greatly reduced. Since the traumatized tissue enveloping it is also a foreign body which will undergo some degeneration, little opportunity is given the living cells to envelop and accept it. Liquefaction with drainage may dislodge it or cause it to be an additional source of irritation. Great care must be observed in surgery so that tissues are not unduly traumatized when one expects to leave foreign bodies within the wound.

One of the greatest problems of foreign bodies comes with their relationship to infection. Being inert and occupying space, they are of the absorbable kind, the very act of absorption creates edema and free fluid which favor bacterial growth. If they are porous, bacteria will remain alive within the foreign bodies and survive the effects of antibiotics and antibacterial drugs, which may give temporary control to the reaction in the living tissues. At a subsequent date, the infection may start again. When a reaction about a foreign body is going on, drainage from a wound will be copious and complete healing will not be accomplished until the foreign material is removed. Tissues which formerly seemed to grasp the material very securely will be found to soften and withdraw from it. Again the only remedy is removal.

It is an accepted fact that foreign bodies left in tissues predispose to infection of the area at any time. A patient who has carried for years a foreign body of one kind or another and has had no difficulty from it may develop an acute reaction and an abscess about the object. Sometimes these are traced to secondary trauma without additional external contamination. At other times the source of the infection is unknown and it is assumed that the organisms are distributed by the blood to an area of lowered resistance.

Local Blood Supply. To interfere with the local blood supply of a wound, even in a healthy individual, is like limiting the raw materials to a good industry. Production will drop off. The process of granulation tissue formation and wound healing is impossible without an adequate blood supply.

The blood supply may be interfered with locally by the injury itself, laceration of regional vessels such as the popliteal artery or pressure of old or new scar tissue. Swelling

corpuscles to stain the tissues, produce a brownish discoloration to the drainage and contribute to the development of anemia in severe infections.

The streptococcus may also produce a fibrinolysin which makes it difficult for the tissues to wall off a streptococcal infection, since granulation tissue is required for this purpose, and the growth of granulation tissue is dependent upon the deposition of fibrin. This enzyme is known as streptokinase and is commercially available for therapeutic use against heavy deposits of fibrin.

Streptodornase is another enzyme complex produced by streptococci. Its action is on the constituents of nuclei and cytoplasm of cells, particularly leukocytes found in pus. Some of the enzymes in the dornase factor are believed to be hyaluronidase, ribonuclease, desoxyribonuclease, nucleotidases and nucleosidases.

Most organisms produce proteinases which assist in the general breakdown of proteins. Special ones, such as collagenase, permit them to penetrate fascial barriers. The human bite infections are famous for this and much of the credit goes to the *Bacteroides melaninogenicus* and the anaerobic streptococcus. The former produces a black pigment and contributes to the putrid smell of lung abscesses, dirty mouths, appendiceal abscesses and infections of the human bite. Its enzymes readily dissolve fascia, ligaments and tendon sheaths to cripple permanently its victims.

Clostridial organisms may work singly or in combination. Some produce strong proteinases, others saccharolytic enzymes which ferment muscle sugar into gas and acid. It is believed that hyaluronidase acts as a spreading factor and assists in the dissemination of their toxins. Other bacteria also produce hyaluronidase presumably for the same purpose. The proteinases of some clostridia are very potent. The proteinase and collagenase of *Clostridium histolyticum* are capable of completely liquefying the muscles and fascia of the extremity of an animal or a man.

Some bacteria, such as the staphylococci, streptococci and clostridia, can produce necrotizing enzymes capable of producing necrosis of tissue by direct contact. In addition, spontaneous bleeding from infected granulation tissue has been associated with the products of growth of certain bacteria. In active infections, combinations of all of these enzymes may assist the microorganisms in their penetration and destruction of the tissues. Edema secondary to infection

may interfere with circulation and foster necrosis, as in gas gangrene.

In brief, toxins produced by bacteria may account for hyperemia, increased capillary permeability, edema, spontaneous bleeding, clotting, clot and tissue liquefaction and fragmentation and death of tissue cells. Moreover, combinations of bacterial toxins possess a synergistic effect. Enzymes liberated from dead and dying cells in combination with bacterial enzymes may further tissue reaction.

Foreign Bodies. A mass which is not normal for the tissues in which it is found is a foreign body. In the broad sense, it is not entirely true that a foreign body is something introduced from the outside. Tissues can produce their own foreign bodies such as urinary calculi, salivary calculi, gallstones, calcium deposits in areas of old injury or uric acid crystals of gout.

Foreign bodies produced by the tissues may be liquid. Following injuries to glandular tissues, their secretions or excretions escape from normal channels and become foreign for the surrounding structures. Examples of this include the distention with saliva of a closed wound of the cheek which has caused damage to the parotid gland, free bile in the abdominal cavity from a ruptured bile duct or a lacerated liver, leakage of pancreatic juice following injury to this gland, extravasation of urine following trauma to the urinary tract, and leakage of gastric or intestinal secretions into the abdominal cavity after perforation of a hollow viscus.

Abnormal accumulations of blood and lymph in tissues may be classed as foreign bodies. Hematomas and fluid accumulations of serum and lymph in large closed wounds are inert materials, abnormal for the tissues, and they are treated by the host as foreign bodies. A mass of tissue which dies and is allowed to remain in place also falls into the category of a foreign body.

Obviously, the reactions will present great variations. To acquire good clinical judgment about the management of foreign bodies, one should analyze their attributes in relation to tissue responses. Most of the reactions to foreign bodies can be traced to the physical and chemical natures of the bodies themselves, the state of health of the tissues about them and the presence of bacteria.

A continuous search is being conducted for metals which are strong, light, noncorrosive, malleable and nonirritating. The ones

Anything that can be done to control or eliminate stasis will benefit wound healing. Elevation of the part for gravity drainage has already been suggested. Compression dressings have been in vogue for years, but they are difficult to apply and their pitfalls are many. During the heat of summer the heavily padded pressure dressings applied to body burns have contributed to the retention of heat and the production of thermal disasters to some patients. Constricting dressings about the thorax and abdomen may cause respiratory embarrassment and pressure dressings on an extremity which do not go all the way to the end will serve to increase the stasis and swelling beyond the bandage.

Hemorrhage. Disregarding the effects on the individual of having a continued loss of blood to deplete his blood volume or his cellular and serum protein reserves, bleeding into wounds does have adverse influences on their healing. Ideally, the coagulum should be just enough to stick the parts of the wound together and to eliminate dead spaces. The effects of blood accumulation beyond this amount, resulting from the injury, or inadequate stasis during operation, are rather clear since the sides of the wound will be forced apart. The resulting hematoma will increase the tension on the tissues to produce pain, ischemia, necrosis and delayed healing. Sutures subjected to the stretching effect of an expanding hematoma may cut through and become loose.

Bleeding in a closed wound will cause the blood to extravasate along planes of least resistance. Bleeding from severe fractures of the pelvis, for example, can extend in the retroperitoneal tissues to the diaphragm, mediastinum and even to the level of the neck. These areas can hold more blood than the patient can afford to lose and death is common following such accidents. The presence of blood in these areas disturbs the innervations to the gastrointestinal tract and favors the onset of ileus.

Extravasated blood in muscle and fascia stiffens the tissues, increases the edema, occludes capillary flow, impairs the flow of lymph and lessens local resistance to infection. Function of a part may be affected by the pain, swelling, stiffness, diminished blood supply and impaired innervation resulting from marked extravasations of blood.

Since extravasated blood cannot return to the circulation as whole blood, it usually clots and slowly undergoes degeneration and absorption, while a part of it is utilized in

the growth of granulation and scar tissues. This, too, increases the morbidity for the injury and leaves behind an undesirable amount of scar to be reckoned with during the convalescence and rehabilitation.

There is no circulation within a hematoma until it becomes organized. Until that time, bacteria within the hematoma cannot be reached by systemic antibacterial drugs. Large hematomas which are slow to absorb and which have not been aided by therapeutic evacuation sometimes end in rigid-wall cavities containing encapsulated fluid.

The effect of blood clots being without circulation can be observed in work with skin grafts. If a hematoma develops beneath a graft it will hold the skin away from its source of nourishment and bring about its death. The bleb may then be opened and the contents evacuated. The surrounding area of graft, having remained viable, may be sufficient to provide epithelial growth to cover the defect or additional grafting may be necessary if the hematoma was large.

General Factors Influencing Wound Healing. *Blood supply.* Since living cells contributing to the process of healing must receive their energy and materials necessary for growth from the circulating blood, any systemic disease which diminishes the blood supply may impair wound healing. Diseases producing anemia, cardiac decompensation, obliterative arterial disease, decreased blood volume and edema may, therefore, have marked effects on the process of healing. The surgeon must, therefore, observe carefully the efficiency of the general circulation in order to determine whether or not healing is possible or if it can be improved by treatment which renders the circulation more efficient. Careful attention should be paid to the status of the cardiac function since digitalization may be required to overcome dependent edema in patients with cardiac decompensation. If the arterial supply to the part is greatly diminished by arteriosclerosis, it may be wise to place the injured leg in a slightly dependent position to augment the local blood supply. The presence of anemia and decreased blood volumes should be determined and corrected. There is suggestive evidence that the poor wound healing observed in severely anemic patients is probably secondary to protein and vitamin deficiencies rather than to the anemic state itself.

Nutrition. A normal physiologic status is essential for a normal and most rapid rate of wound healing. Alterations in the physiologic

from contusion, congestion, infection or toxins from bites of poisonous animals serves to cut down the local supply of blood. Whatever the cause, impairment of wound healing occurs.

Signs of retardation in healing appear. The formation of granulation tissue is retarded and the tissues become pale. If blanching is produced by digital pressure, the return of circulation is sluggish. The skin is cool and wounds are slow to epithelize and contract. The line of incision shows little hyperemia and is easily separated. The open wound shows pale, wet, soft granulations which grow sluggishly or fail to grow at all. Purulent exudation is minimal, but bacterial growth is likely to increase tissue destruction. Skin flaps are readily lost and grafts may fail to take or are easily dislodged by activity.

Elective surgery should not be attempted on tissues known to have poor blood supply. In an emergency, everything possible should be done to improve the condition accounting for the disorder.

In the care of wounds of violence involving tissues which are otherwise normal, the surgical therapeutic effort to remove devitalized tissues from the margins of these wounds is based in part on the appreciation of the contribution of a good blood supply toward prompt healing. Apposition of tissue with an assured supply of blood is most desirable. Flaps with precarious blood supply must not be impaired with constricting bandages and tight or excessive sutures. Excessive scar tissue with deficient circulation which affects the recovery of a part should be excised to a good source of blood and the defect corrected by a suitable graft.

When ischemia develops in tissues which have no impairment of sensation, marked pain develops. Whether it is produced by an arterial embolus, tight dressing, tight cast, tight sutures or a distended wound, the mechanism is similar. This can be appreciated through two simple experiments. Place a blood pressure cuff about the arm and inflate it to a degree well above the systolic pressure. Record the time and see how long it can be tolerated. Second, sit in a chair and obtain the most comfortable position possible. Extend the legs on a foot stool if you wish, and pick up an interesting book. From then on do not change the position. When ischemia begins to develop over the heels, calves, knees, ischial tuberosities, sacral area or over the greater trochanter of the femur because of the continued pressure, the pain

will become disturbing enough to interfere with the reading. Record the time, and do not move. When it becomes most unbearable, think of the infant being given an intravenous injection in a leg which is strapped too tightly to a splint, or the patient who has a lump in his cast, or the bedridden creature who cannot change his position but is turned every four hours by a nurse. What part of four hours can you sit without moving?

Edema and Lymphatic Obstruction. When stasis of lymph and venous blood begins to pile up in a wound, the efficiency of healing begins to wane. When lymph flow is obstructed, edema results. When venous flow is obstructed, venous engorgement and edema result. Oxygen tension in the tissues is reduced, carbon dioxide builds up; the pH falls, tissue edema increases, and more stress is placed upon the lymphatic channels. Tissue metabolism slows and the by-products of metabolism begin to accumulate in the tissues to produce a sense of fatigue and malaise.

Lymphatic or venous blockage produces swelling which is detrimental to wound healing and favors bacterial growth. The drainage of open wounds increases. Vesicles may appear in the skin which may break down and form open wounds. Tissues, boggy from edema, will have a restricted blood supply. Capillaries and venules which do not become occluded with clot will be obstructed by pressure. Fibrosis in tissue is enhanced by stasis but fibrosis is not a desirable reaction when it extends beyond the healing of the wound itself. Fibrosis in tissues about a wound weakens the resistance of those tissues to future injury and retards the repair of those injuries.

Excellent examples of the effects of lymphatic and venous stasis are found in the lower extremity. Injuries in the lower third of the leg heal more slowly than in any other part of the body. Acute and chronic ulcerations occur frequently and become complicated by fibrosis and cicatrization. While other factors enter into the problems of wound healing for the lower extremities, stasis of blood and lymph is a common denominator of all of them.

The part played by stasis in delaying the healing of wounds is evident when one observes an ambulatory patient's leg ulcer of long duration heal rapidly as soon as the patient is placed at bed rest with the extremity elevated. The improvement which comes with bed rest is the result of correcting the stasis accompanying the upright position.

Anything that can be done to control or eliminate stasis will benefit wound healing. Elevation of the part for gravity drainage has already been suggested. Compression dressings have been in vogue for years, but they are difficult to apply and their pitfalls are many. During the heat of summer the heavily padded pressure dressings applied to body burns have contributed to the retention of heat and the production of thermal disasters to some patients. Constricting dressings about the thorax and abdomen may cause respiratory embarrassment and pressure dressings on an extremity which do not go all the way to the end will serve to increase the stasis and swelling beyond the bandage.

Hemorrhage. Disregarding the effects on the individual of having a continued loss of blood to deplete his blood volume or his cellular and serum protein reserves, bleeding into wounds does have adverse influences on their healing. Ideally, the coagulum should be just enough to stick the parts of the wound together and to eliminate dead spaces. The effects of blood accumulation beyond this amount, resulting from the injury, or inadequate stasis during operation, are rather clear since the sides of the wound will be forced apart. The resulting hematoma will increase the tension on the tissues to produce pain, ischemia, necrosis and delayed healing. Sutures subjected to the stretching effect of an expanding hematoma may cut through and become loose.

Bleeding in a closed wound will cause the blood to extravasate along planes of least resistance. Bleeding from severe fractures of the pelvis, for example, can extend in the retroperitoneal tissues to the diaphragm, mediastinum and even to the level of the neck. These areas can hold more blood than the patient can afford to lose and death is common following such accidents. The presence of blood in these areas disturbs the innervations to the gastrointestinal tract and favors the onset of ileus.

Extravasated blood in muscle and fascia stiffens the tissues, increases the edema, occludes capillary flow, impairs the flow of lymph and lessens local resistance to infection. Function of a part may be affected by the pain, swelling, stiffness, diminished blood supply and impaired innervation resulting from marked extravasations of blood.

Since extravasated blood cannot return to the circulation as whole blood, it usually clots and slowly undergoes degeneration and absorption, while a part of it is utilized in

the growth of granulation and scar tissues. This, too, increases the morbidity for the injury and leaves behind an undesirable amount of scar to be reckoned with during the convalescence and rehabilitation.

There is no circulation within a hematoma until it becomes organized. Until that time, bacteria within the hematoma cannot be reached by systemic antibacterial drugs. Large hematomas which are slow to absorb and which have not been aided by therapeutic evacuation sometimes end in rigid-wall cavities containing encapsulated fluid.

The effect of blood clots being without circulation can be observed in work with skin grafts. If a hematoma develops beneath a graft it will hold the skin away from its source of nourishment and bring about its death. The bleb may then be opened and the contents evacuated. The surrounding area of graft, having remained viable, may be sufficient to provide epithelial growth to cover the defect or additional grafting may be necessary if the hematoma was large.

General Factors Influencing Wound Healing. *Blood supply.* Since living cells contributing to the process of healing must receive their energy and materials necessary for growth from the circulating blood, any systemic disease which diminishes the blood supply may impair wound healing. Diseases producing anemia, cardiac decompensation, obliterative arterial disease, decreased blood volume and edema may, therefore, have marked effects on the process of healing. The surgeon must, therefore, observe carefully the efficiency of the general circulation in order to determine whether or not healing is possible or if it can be improved by treatment which renders the circulation more efficient. Careful attention should be paid to the status of the cardiac function since digitalization may be required to overcome dependent edema in patients with cardiac decompensation. The improvement which comes with bed rest is the result of correcting the stasis accompanying the upright position.

veloped. In some instances, incisional hernias developed. Microscopic examination of the scarred areas showed degenerative changes in the collagen.

Some of the components of *vitamin B complex* should be added to large doses of *vitamin C* and given to patients after injury or operation. It is suggested that during a period of acute stress after injury and for two or three days afterwards, the patient should receive 1 gm. of *vitamin C*, 50 mg. of *nicotinic riboflavin* and 500 mg. of *nicotinic acid* daily. Thereafter, smaller doses of the vitamins are recommended until recovery is complete.

One of the fundamental roles of *vitamin A* in the body is concerned with maintenance of the integrity of epithelial tissue. Lack of *vitamin A* may lower local resistance to infection. Since this vitamin unites with proteins to become an essential constituent of all specialized epithelial tissues, adequate stores are essential for epithelization following operations or injuries. In indolent ulcerations, in which the infection has been completely controlled, inhibition of wound healing may persist until large doses of *vitamin A* are given systemically. On the other hand, the contention that topical applications of *vitamins A and D* in the form of cod liver oil stimulate wound healing has not been proved.

Vitamin K has an essential role in the control of hemorrhage in relation to a deficiency in prothrombin known as *hypoprothrombinemia*. It is of great importance in patients who are jaundiced or who have marked hepatic insufficiency. Continued bleeding in wounds of such patients will result in improper or delayed healing. Under such circumstances, the administration of *vitamin K* is of great help in producing effective clotting of blood and in preventing continuous oozing into the wounds.

Adequate intake of *vitamin D* is required for the proper absorption of calcium and its deposition in bones. At times it is desirable to pay special attention to the intake of *vitamin D* in connection with the healing of wounds or infections involving bones. Liver impairment following surgical procedures may interfere with the absorption and utilization of *vitamin D*. The need for supplementation which exists following ordinary operations becomes greater when bones are involved in the lesion.

Temperature. Temperature has an effect on the growth of cells and, therefore, on wound healing. In tissue cultures, this effect

is well known. It is probable that the ideal temperature for the healing of a wound is the normal body temperature and that every effort should be made to approximate it with regard to dressings and atmospheric conditions for a wound. Patients subjected to refrigeration anesthesia or refrigeration treatment for prolonged periods may show a marked tendency toward nonhealing.

Rest. Rest of the part is of considerable importance, particularly in relation to wounds of the extremities in the region of joints. Motion of the area by joint or muscular activity disturbs the medium in which the cells are growing and invites extravasation of blood and fluid. However, in abdominal wounds the experience of the past fifteen years has amply demonstrated that the healing of properly sutured wounds is not retarded significantly by early ambulation.

Metabolic diseases. Metabolic diseases such as *diabetes* and *portal cirrhosis* may be factors which inhibit wound healing. In the case of uncontrolled *diabetes*, a decreased resistance to bacterial infection may increase bacterial destruction of tissues in wounds and cause protracted delays in wound healing. In addition, obliterative peripheral arterial disease associated with *diabetes* may affect the local blood supply and the process of healing. In *portal cirrhosis*, *hypoproteinemias*, *hypoprothrombinemia* and *vitamin deficiency* states may influence the rate of healing of wounds.

Uremia. The experience of the Research Team of the U. S. Army in Korea during the Korean War showed that wound healing was significantly retarded in uremic states which developed in some battle casualties as the result of massive tissue necrosis or infection. Wound healing in civilian patients with *uremia* likewise appears to be retarded. The reasons for this are not clear.

HEALING OF SPECIAL TISSUES

Epithelium has marked powers of regeneration and injuries involving the skin and mucous membrane are usually followed by rapid repair and more or less complete restoration of the typical cellular arrangement produced by regeneration. Mucous membranes of the squamous type behave much the same as skin.

Tendons heal by regeneration through the process of granulation. A moderately rapid growth of granulation tissue replaces the exudate between the sutured ends of tendons and fibroplastic proliferation occurs within the granulation tissue. New collagen tissue

state may have deleterious effects on the healing process and must, therefore, be corrected. Malnutrition or diet deficiency may be the cause of lowered resistance in patients. Difficulty in maintaining cellular nutrition may result in failure of the body to mobilize the defense mechanism and may even cause local conditions favoring the growth of invading bacteria.

In some patients with infections it has been found that there is a complement deficiency in the blood. This is a nonspecific element in the blood necessary for defense against invading bacteria.

A deficiency in protein, known as *hypoproteinemia*, inhibits fibroplasia within the granulation tissue. Hypoproteinemia may be caused by prolonged protein starvation or by loss of protein following severe or repeated hemorrhage, prolonged sepsis, continued inflammatory exudate, drainage from fistulae, cirrhosis of the liver or ascites. It is frequently associated with tissue edema produced by a loss of fluid from the capillary bed into the intercellular spaces. In the presence of protein deficiency, the edges of a wound appear soggy with edema and they may give no evidence of fibroplasia as late as the eighth to fourteenth day after injury. In wounds of rats suffering from protein depletion, it has been shown that the quantity of mucopolysaccharides and collagen per gram of tissue is less and that the time required for their production is increased over that for normal animals. This may result in disruption of abdominal wounds. It is essential to determine the presence of hypoproteinemia by measuring the values for serum protein and to combat any hypoproteinemia by transfusions of plasma or blood and a diet rich in protein before and after operation.

During the period immediately after injury or operation, a state of negative protein balance is common. An increased protein intake may restore a positive balance and provide more adequate nutrition.

Lyons has emphasized that delayed wound healing may be observed in patients with a reduced total serum protein volume and a reduction in blood volume associated with severe wounds or protracted illnesses. Such patients are also in negative protein balance. The observed serum protein and hemoglobin levels may be normal in patients with decreased circulating blood volume. Under such conditions, the administration of liberal amounts of blood to patients who have lost

10 to 20 per cent of their body weight usually is followed by improved wound healing.

Agammaglobulinemia is a state of deficiency of a special protein, *gamma globulin*, in the blood which decreases the patient's resistance and favors the development of infections resistant to treatment.

Vitamins. It is well recognized that surgical procedures and injuries diminish hepatic function and that the liver is concerned with the metabolism and storage of most of the vitamins. Replacement therapy is generally considered helpful in maintaining the body at optimum efficiency since some of the vitamins play an important role in the healing of wounds.

Several of the vitamins have been shown to have special significance in the relation to healing of the wounds and infections. *Vitamin C* is required for the production and maintenance of the intercellular cement, especially in the capillary bed and in the collagenous tissues. Lack of, or deficiency of, intercellular substance in the granulation tissues and capillary bed results in hemorrhage into the wound space and into the bordering tissues, prolongs the lag period, retards fibroplasia and delays the development of adequate tensile strength in the wound. A study by Dunphy of surgical wounds made in rats living upon diets deficient in *vitamin C* showed that fibroplasia progressed well and ground substance was present in adequate amounts. The animals were unable to utilize the basic materials for the production of collagen, however, except in the presence of *vitamin C*.

Vitamin C is also involved in protein metabolism through its effect on tyrosine and phenylalanine metabolism. Experimental studies of Lind and Crandon indicate that minor degrees of *vitamin C* deficiency are not very important from the standpoint of wound healing. However, prolonged deficiency is associated with marked interference with the healing process. Like hypoproteinemia, *vitamin C* deficiency may be a causative factor of wound disruption or dehiscence. *Vitamin C* is essential to the normal healing of wounds and to the maintenance of their strength. Pirani and Levenson have reported evidence that scar tissue seems to be more sensitive to *vitamin C* deficiency than is normal connective tissue. In normal guinea pigs who were injured, allowed to heal for six weeks and then started on diets deficient in *vitamin C*, the previous scar became swollen and hemorrhagic when scurvy de-

is formed and produces firm union of the severed ends. Studies of Mason have shown that the tendon ends start to proliferate about the fourth or fifth day after suture and to send out bands of cells and fibrils into the adjacent tissue. If the tendon is injured or if it is stripped of its blood supply, necrosis is likely to occur and delay the

great, it may be bridged by proliferating cells of the tendons themselves.

Muscle does not regenerate but heals by granulation and scar tissue formation. Proliferation of fibrous tissue from the muscle sheath and the intermuscular septa forms new fibrous collagenous tissue which unites the separated muscle and restores its function. A minimal amount of scar tissue necessary to fill the wound defect in the muscle is advantageous, since it is apt to produce less interference with the function of that muscle. Healing of muscle injuries will not progress until all necrotic and devitalized muscle is removed.

Bone heals by regeneration. It has remarkable powers of healing after injury. A clot first forms between the two ends of fractured bones. Thereafter, typical proliferation of granulation tissue develops from the endosteum, the periosteum and the haversian canals, along with the formation of capillary buds. The osteoblasts in the periosteum and endosteum proliferate and lay down new osteoid tissue. The clot is absorbed and replaced by vascular tissue and new osteoid tissue. Calcium salts are then deposited in the osteoid tissue making it firm and known as *callus*. The superfluous, or excessive, external callus is largely or completely absorbed until the normal contour of the bone is restored. Healing occurs more rapidly in long bones than in flat bones. Bones with little or no periosteum are apt to heal slowly. Immobilization of fractured bones is particularly essential for healing. The repair of bone at the site of injury or infection may be so complete that it may be impossible to detect after one year.

Cartilage may or may not heal by regeneration, depending upon its location. Articular cartilage in joints does not regenerate, whereas costal cartilages can regenerate provided the perichondrium is present and viable. Only the latter produces parent cells capable of producing adult chondrocytes which reproduce cartilage.

Composed of mesothelium, serous mem-

branes, such as the peritoneum, have great powers of regeneration. Denuding of peritoneum from large areas of the wall of the abdominal cavity has been shown to be followed by early regeneration of the peritoneal surface.

As soon as the surfaces of the mucous membrane of the *gastrointestinal tract* are united by suture an exudate forms and seals the union. This exudate is invaded by granulation tissue from the subserous connective tissue. Healing is usually more rapid than in other epithelial tissue. The united mucosa which has been inverted into the lumen by the suture undergoes more or less necrosis along the suture line. As this sloughs off, however, granulation tissue forms and is then replaced by new mucous membrane which may in every way resemble the normal tissue. Thus, healing is by granulation of the entire wall except the mucous membrane, where it is by epithelial regeneration. Mucous membrane of the *gastrointestinal tract* has exceptional powers of regeneration.

Components of *nervous tissue* do not regenerate unless a neurilemma sheath is present. Nerve cells which have been destroyed do not regenerate. However, the various fibers of the cell may regenerate when the cell itself remains viable. Division of a peripheral nerve may be followed by growth of the axon in a peripheral direction and function may be restored. The connective tissue which grows more rapidly than the nerve fibers may surround them and impede their further growth. Wounds of the brain and spinal cord heal by the proliferation of the glial-supporting tissue.

creased rather than decreased the necessity for precise diagnosis. Specific infections, and not clinical syndromes, must be treated.

NATURAL MECHANISMS OF NONSPECIFIC RESISTANCE TO INFECTION

The human body is constantly exposed to a variety of microorganisms. Certain varieties are resident normally on the external and internal surfaces of the body. Others are present on inanimate objects in the environment. In health, man lives in equilibrium with the microorganisms to which he is constantly exposed. This tolerance is due to a system of anatomic, physiologic and cellular defenses which afford protection against the microbial hazards of everyday life.

The anatomic (mechanical) barriers to invasion by microorganisms are both external and internal. The external defenses include the epithelial surfaces of the skin, respiratory tree, gastrointestinal tract and urinary tract. Hair follicles and secreting glands in skin and mucous membranes are potential avenues of invasion of bacteria into deeper structures. To ensure protection against infection by external barriers, clean wounds are promptly closed by suture or skin graft. Examples of internal barriers are the fascial planes, the muscle compartments and the serous membranes, such as pleura and peritoneum. These internal barriers govern, to some degree, the direction and spread of infection.

Physiologic defenses against infection which dilute or discharge bacteria are exemplified by the washing and diluting action of tears, saliva, mucous secretions, gastric juices and bile, and by the mechanical emptying of the intestinal and urinary tracts.

The principal cellular defenses are the phagocytes and reticuloendothelial cells, which clear bacteria and their products from the tissues and the blood stream. Their action is enhanced by circulating antibodies (globulins) and other nonspecific antimicrobial systems, such as complement. The production of specific circulating antibodies, as in the response to the injection of tetanus toxoid, is the basis for attempting to immunize an individual against a particular disease.

PRINCIPAL MICROORGANISMS OF SURGICAL IMPORTANCE

The great majority of diseases are caused by microorganisms which come from human carriers. Others are caused by microorganisms from sources external to the body. In

most situations the nature of the offending microorganisms is more important in determining specific therapy of infections than is their source. For this reason, knowledge of the principal types of microorganisms and the infective processes associated with their activities is of fundamental importance in diagnosis and treatment.

The three major groups of microorganisms that have a causal relationship to infections are the bacteria, the fungi and the viruses. Fortunately, most bacteria and fungi can be stained easily and studied by relatively simple techniques and their sensitivities to chemotherapeutic agents can be estimated in vitro. Bacterial infections are encountered most frequently. Bacteria may be gram-positive, retaining crystal violet, or gram-negative, releasing crystal violet and taking on the counterstain. They vary in size and shape and, in this respect, are grouped as cocci, bacilli or spirochetes. They may grow aerobically or anaerobically. In clinical infections they may be present singly, as in hemolytic streptococcal cellulitis, or they may be present in a combination of several species, as in acute secondary peritonitis, bronchiectasis and burns sepsis.

GRAM-POSITIVE BACTERIA

Staphylococci. The most numerous infections are those caused by the ubiquitous staphylococci, such as *Staphylococcus aureus* or *albus*. Staphylococci are known to produce a whole range of metabolites: hemolysins, leukocidin, fibrinolysin, hyaluronidase, coagulase and enterotoxin. In some way, these metabolites influence the diverse manifestations and course of staphylococcal inflammations. There is hardly a tissue or system of the body which may not be the site of staphylococcal involvement. These organisms manifest themselves clinically in three principal forms.

Circumscribed purulent necrotic lesions are the most common and may involve any site of the body. They may be localized, locally invasive or associated with bacteremia, with or without metastatic abscess. Response to treatment characteristically is slow and the staphylococci persist until cure is complete. Antibiotic sensitivities vary according to the antibiotic and the duration and intensity of its communal usage. Bacteremia may also arise as a complication of cannulation of a vein and intravenous administration of fluids. The lesions of soft tissues seen most frequently are paronychias, furuncles, carbuncles and postoperative

EDWIN J. PULASKI is at present Chief of the Department of Surgery at the United States Army Hospital, Fort Dix, New Jersey, and holds the rank of Colonel in the Army Medical Corps. Born in Pennsylvania, he graduated from the University of Pennsylvania and its medical school. After his residency training in surgery at Columbia University-Presbyterian Hospital, he devoted himself to the study of surgical bacteriology. He was the founder and first chief of the Army Surgical Research Unit and chief of the Army's streptomycin research program. He has continued to contribute to the knowledge of infections and their response to various methods of control.

The term "infection" denotes an inflammatory condition attending the entry and multiplication of microorganisms in the body. There are many factors from which are derived the principles of prevention and treatment of those infections of concern to the surgeon.

The symptoms and characteristics of clinical infections differ greatly with the species and virulence of the causal pathogens, the tissues and anatomic parts of the body affected, the general condition of the individual and the extent and duration of the infection. The presence of microorganisms on the skin and mucous membranes of the body and in fresh traumatic wounds is not "infection" but is "contamination." Patients who require surgical procedures in such situations are referred to as "contaminated cases." The distinction between contamination and infection is sometimes difficult. Adverse changes may be manifest only by delayed healing, excessive scarring or failure of "take" of skin grafts.

In the prechemotherapy era, infections were designated as "surgical" when they were treated by operation. Since the avail-

ability of chemotherapy, this designation has excluded many cases that formerly would have been included in the surgical category. At present there are three types of infections important to the surgeon: (1) suppurative inflammations having a course profoundly influenced by surgical intervention; (2) infections complicating operative procedures, and (3) incidental or concurrent infections in body sites remote from the field of operation.

The present knowledge of prevention and treatment of microbial diseases stems from the development of aseptic techniques since Lister and from advances in bacteriology, immunology and antimicrobial therapy. The greatest advance has been the discovery of the antibiotics. As a result, a significant decline has occurred during the last two decades in the once uncontrolled streptococcal, pneumococcal and clostridial infections among patients in surgical wards. Other infections, nevertheless, have not disappeared since the advent of antimicrobial therapy, and their threat remains a continued source of anxiety in all fields of surgical endeavor. Furthermore, antibiotic therapy has in-

of animals and man. The germination of implanted spores and multiplication of vegetative bacteria can come about as a result of ischemia, the presence of calcium salts (soils), the deoxygenation of tissue by proliferating aerobic bacteria, or by autolysis of dead tissues. Toxicogenic clostridial infections are unique since the clinical picture is determined by their toxins and products of breakdown of involved tissues. Prevention and treatment are surgical, immunologic and antibiotic.

Under proper conditions, *Cl. tetani* proliferates at the site of its lodgment without any characteristic changes in the local wound. It elaborates a toxin of extreme potency. The incubation period is four days to three weeks or longer, depending somewhat on the character, extent and location of the wound. The toxin passes along peripheral nerves to reach the anterior horn cells where its action results in characteristically painful muscular contractions, primarily of the masseter and neck muscles, and secondarily of the trunk. These contractions can be reproduced in experimental animals by injecting purified toxin. Active immunity is produced by tetanus toxoid; passive immunity by tetanus antitoxin.

Clostridial myositis (gas gangrene) is a rapidly spreading edematous myonecrosis developing in severe wounds of muscle and bone. It results from the invasion of ischemic muscle by the genus *Cl. perfringens*. *Cl. perfringens* occurs most frequently. Changes in other organs include necrosis in the kidneys and degenerative changes in the liver. A filtrate of *Cl. perfringens* contains a galaxy of enzymes, including alpha toxin (lecithinase), leukocidin, fibrinolysin, collagenase and hyaluronidase. Experimentally, the principal lethal factor is alpha toxin (lecithinase), affecting capillary endothelium and sarcolemma. This factor, plus the modification of the ground substance by the action of hyaluronidase and fibrinolysin, is responsible for the development of wet gangrene. Collagenase also plays a part in the local spread of clostridial infection. The widespread metabolic disturbance is probably associated with the peripheral vascular failure that is a late characteristic of the disease. Since the availability of penicillin, enthusiasm for polyvalent gas gangrene antitoxin therapy has waned. Toxoids for active immunity are in the developmental stage.

Clostridial cellulitis is a serous crepitant

process of subcutaneous, retroperitoneal or areolar tissues produced by one or more of the clostridia, usually *Cl. perfringens*. In contrast to gas gangrene, muscle invasion is absent and systemic effects are less pronounced.

Puerperal clostridial septicemia is an infection which becomes lethal rapidly unless vigorously treated and is characterized by sudden intravascular hemolysis and peripheral circulatory failure.

THE GRAM-NEGATIVE BACILLI

The principal gram-negative bacilli of surgical importance are the coli-aerobacter-aerogenes groups and the various species of *Proteus* and *Pseudomonas*. They constitute a large part of the normal intestinal flora and ordinarily they are not harmful within the colon. When they reach tissues outside the intestinal tract they cause disease, particularly in the lungs, the urinary apparatus, biliary tree, peritoneum, blood stream, meninges and necrotic tissues. Antibiotic sensitivities of gram-negative bacilli vary with the species and individual strains within species. Treatment is directed at correcting underlying pathology, eradicating the locus of infection and adjunctive antimicrobial therapy.

Gram-negative infections of the urinary tract are manifested by inflammation and smooth muscle spasm, dysuria and pyuria.

Infections of the biliary apparatus usually accompany inflammations due to obstruction or biochemical disorders.

Acute bacterial peritonitis is usually polybacterial, the gram-negative bacteria constituting an important part of the total flora. Included are anaerobic forms (*Bacteroides* species), which are present also in mixed putrid infections of wounds and of the perineum. *Escherichia coli* and other coliforms do not produce a foul odor when growing in sterile pus. The putrid odor of appendiceal peritonitis is primarily the result of proliferation of anaerobic bacteria, principally Clostridia, *Bacteroides* and anaerobic streptococci.

The usual portal of entry for gram-negative bacilli causing bacteremia is the genitourinary tract, the gastrointestinal tract or an extensive thermal or traumatic wound. Bacteremia from these organisms may also be caused by transfused, contaminated whole blood or unsterile solutions used parenterally. The protein-lipid polysaccharide endotoxins of gram-negative bacilli all have similar effects following intravenous admin-

wound infections. Parotitis and abscesses of dental origin are frequently staphylococcal. The soft tissue infections may be precursors of more serious infections such as bacteremia, osteomyelitis, meningitis or pneumonia. Metastatic staphylococcal abscesses may occur in the brain, lung, kidney, perirenal tissues or prostate.

Another form is staphylococcal enterocolitis, a widespread membranous lesion occurring in the intestinal tract as a sequela of overgrowth of staphylococci, as an incident of antibiotic therapy, or from some obscure cause following resection of the stomach or colon. Its features are cholera-form diarrhea, circulatory collapse and passage of sloughed mucosa.

The third form is the severe shocklike syndrome of staphylococcal food poisoning attributed to preformed enterotoxin elaborated by staphylococci.

Staphylococcus aureus is now classified by bacteriophage typing of individual strains into four broad groups (I, II, III and IV). Each group is further comprised of a large number of subtypes. No particular group of staphylococci is exclusively associated with any type of staphylococcal lesions. Strains resistant to penicillin and other antibiotics frequently are of the Group III variety, but not exclusively. Bacteriophage typing is a valuable tool in the epidemiologic investigation of outbreaks of staphylococcal infection.

Streptococci. Streptococci are classified according to their ability to hemolyze the blood added to agar plates. Beta hemolytic streptococci elaborate an array of substances—erythrogenic toxin, streptolysin, leukocidin, hyaluronidase, streptokinase and desoxyribonuclease. Erythrogenic toxin is associated with the rash of scarlet fever. Hyaluronidase assists in the penetration of intracellular cement substances by hydrolyzing mucosubstances. Streptokinase and the ribonucleases are capable of dissolving fibrin and liquefying purulent exudates. In purified form, they find therapeutic application for liquefying blood clots and thick pus. These multienzymatic activities explain the spreading character of hemolytic streptococcal cellulitis and lymphangitis. Colonization of granulating wounds, so-called silent infections by beta hemolytic streptococci, is one cause of failure of skin grafts to "take." The organisms produce a lysis of the fibrin "cement" that fixes the graft to the wound surface.

The resistance of hemolytic streptococci to antimicrobial agents is rare. The presence

of a microaerophilic hemolytic streptococcus is associated with a rare, progressive ulceration of the skin and subcutaneous tissues—the chronic, burrowing, undermining ulcer described by Meleney. Sensitivity of this organism to antibiotics varies.

Nonhemolytic and alpha hemolytic (*Streptococcus fecalis*, *Streptococcus viridans*) streptococci are usually less virulent than the beta hemolytic variety. Nonhemolytic streptococcal infection does not have characteristic clinical features. For this reason, identification of the organisms and culturing for sensitivity to antibiotics are important as guides to therapy. Singly, or in combination with other organisms, the nonhemolytic streptococci and *Str. viridans* are associated with the abscesses of dental caries, liver abscesses, subacute bacterial endocarditis and infections of the urinary tract. They are frequently found in the peritoneal exudate following perforations of the duodenum and in empyema of the gallbladder. They are present in the mixed flora of peritonitis following perforation of the appendix or colon.

Anaerobic streptococci, singly or in combination with other forms of bacteria, are associated with streptococcal myositis, puerperal sepsis, perirectal and intra-abdominal abscesses, wound infection from a human bite, chronic synergistic gangrene of the abdominal or chest wall and lung abscess. Their presence should be suspected when streptococci are found microscopically in stained smears of pus but are not recovered bacteriologically in routine aerobic cultures.

Mycobacterium Tuberculosis The tubercle bacillus is a gram-positive and acid-fast organism producing the well-known disease of tuberculosis. The surgeon encounters this disease most frequently in the pulmonary, lymph node, abdominal, renal and osseous forms.

Bacillus Anthracis. An important aerobic pathogenic gram-positive bacillus, *B. anthracis* is the causative agent of anthrax (malignant pustule), sometimes confused with pyogenic coccal infection of the skin.

Spirochetes. These are less commonly encountered in surgery than the cocci and bacilli. Those of major surgical importance are the *Treponema pallidum* of syphilis, the *Borrelia vincenti* of Vincent's angina and the *Spirillum minus* of rat-bite fever.

Toxigenic Clostridia. *Clostridium tetani* and the group of toxigenic clostridia associated with gas gangrene are widely distributed in nature, including soil and feces

bacteria indigenous to a particular area of the body, as in acute appendicitis.

Resistance to infection may be decreased by mechanical or functional disturbances or by a combination of these two factors. Examples of mechanical disturbances are wounds of violence, thermal injuries, congenital anomalies, and obstructions of organs, such as the bronchus, the ureter, the common bile duct and the appendix. Examples of functional disturbances are biochemical inflammations, such as phlebitis, cholecystitis and allergies in the skin or respiratory tract. In a few instances bacteria may penetrate mucous membranes without trauma, as in typhoid fever, amebic or bacillary dysentery and tuberculosis. Infection (superinfection) may also arise as a complication of antibiotic therapy in the absence of prior tissue damage, e.g., staphylococcal pneumonia, diarrhea or secondary infection in the urinary tract.

Bacteria not only must enter, but also must multiply in tissues before they can produce harmful effects. The microorganisms freshly implanted in tissues may be so few in number, or of such low pathogenicity, that they are destroyed by defensive mechanisms of the body without clinical evidence of inflammation. This accounts for the failure of infection to develop in every open wound. If the number and character of the invaders are sufficient to overpower the resistance of the tissues, the bacteria multiply; they also release toxic metabolites and gain a foothold at the site of lodgment.

Local Effects. The response of the host is to localize and eradicate infection by means of inflammation—a reaction which manifests itself locally and systemically. The proliferating microorganisms and their metabolites act as stimuli to which the tissues respond by a series of interrelated progressive phenomena: (1) localized cellular destruction, (2) increased capillary permeability and formation of edema, (3) stickiness of the endothelium and (4) margination of leukocytes and entrance of various cells into the injured tissue. One or another phase may be inconspicuous or predominant, depending upon the bacterial species.

The reaction of inflammation is an attempt on the part of the body to localize the proliferating bacteria at their portal of entry and thus prevent their general dissemination. Globulins, antibodies and fibrinogen pass into the affected area, creating a fibrin network and thrombi, which prevent the infected material from leaving the area. Cer-

tain species of bacteria may enhance fibrin formation (staphylococci); others may retard its formation or actually destroy it (*Cl. perfringens*, hemolytic streptococci).

The effort at fixation is accompanied by the accumulation of phagocytes and reticulo-endothelial cells. Phagocytosis is retarded by reduced blood flow, as in shock and reduced body temperature, and by deprivation of oxygen, as in larger accumulations of pus.

As the leukocyte wave deteriorates, macrophages from the local tissues and the blood make their appearance. They increase in number remarkably and actively phagocytose and digest the invading bacteria. Specific antimicrobial therapy, by means of bacteriostatic or bactericidal action, assists phagocytic activity. The development of macrophages into fibroblasts supplies the active elements for regeneration and repair, formation of scar tissue and the walling off of foreign bodies.

The longer a microbial inflammation persists, the more harmful its effect becomes. In addition to necrosis, abscess formation and retardation of absorption of exudate may prevent collapse and apposition of the tissues and may cause formation of a persisting sinus or fistula. In certain organs, such as brain, liver or lung, function may be seriously impaired. Crippling adhesions may form on serous membranes such as pleura, joints or bowel.

Exudate may be absorbed by lymphatics; it may spread or be converted to pus or be vascularized, i.e., form granulation tissue. Stated in another way, the infection may evolve by (1) restoration of tissues to normal, as in hemolytic streptococcal lymphangitis; (2) localization, abscess formation, resolution and scar formation, as in carbuncle; (3) granulomatous reaction, as in any chronic inflammation, e.g., actinomycosis, or (4) dissemination of the infection. The route of spread may be by continuity, as in phlebitis; by contiguity, as in osteomyelitis from paronychia; by lymphatics, as in streptococcal cellulitis; or via the blood stream through blood vessel erosion.

Systemic Effects. The metabolic alterations and systemic manifestations of infection are reflections of the extent and severity of the disease. Breakdown products of bacteria and tissue proteins act upon the heat-regulating center, altering the thermostatic level at which body temperature is regulated. Chills are associated with vasoconstriction. Failure to lose body heat results in fever. When vasodilation and sweating take place,

istration: chills, fever, prostration and varying degrees of peripheral circulatory failure. Bacteremia is difficult to eradicate and may be lethal

Gram-negative bacillary meningitis produces no specific manifestations and is diagnosed by bacteriologic studies.

Many species of gram-negative bacilli cannot digest total proteins, i.e., they cannot invade living tissues, but they can assimilate amino acids and peptides. Proteolytic enzymes in dead or devitalized tissue and in pus provide degraded proteins which act as a nutritional pabulum for the growth of gram-negative bacilli. Their enzymes are capable of producing lysis of a blood clot and of exciting a discharge that is persistent and interferes with tissue repair. The discharge may be irritating and cause excoriation of skin. Drainage of pus and removal of dead tissue and debris are necessary for complete eradication. Scar formation, sinuses and fistulae are frequent sequelae of persisting gram-negative infections of soft tissues and bones

Proteus, like other gram-negative bacilli, usually produces infection only when found outside its normal habitat—the intestinal tract. *Proteus* microorganisms tend to increase in number in the bowel when coliform bacteria are suppressed, e.g., after broad-spectrum antibiotic therapy. Diarrhea may result.

Pseudomonas species are pathogenic when introduced into areas devoid of natural defenses or in the presence of other pathogenic organisms. They cause infections of wounds and burns, meningitis when introduced by lumbar puncture, and urinary tract infection when introduced by catheters or unsterile solutions. A characteristic green pus is formed

Gram-negative bacillary infections encountered less frequently are those caused by *Salmonella*, such as typhoid bacilli and paratyphoid bacilli. Their manifestations include intestinal perforation, cholecystitis, periostitis or abscesses of soft tissues and bone. Other gram-negative bacillary infections include chancreoid caused by *Hemophilus ducreyi* and granuloma inguinale caused by *Donovania granulomatis*. Tularemia is caused by *Pasteurella tularensis*, the local manifestations being a nonhealing ulcer on the hands or face and enlargement of the regional lymph nodes.

FUNGI

Fungal diseases may be superficial or

deep seated. Epidermophytosis of the feet, an example of a superficial mycosis, is frequently the portal for spreading pyogenic infection. Erysipeloid, commonly known as "fish-handler's disease," is a cutaneous disease of the hands due to *Erysipelothrix rhusiopathiae*, which affects those who handle dead animal matter. The deep mycoses, such as actinomycosis, blastomycosis, coccidioidomycosis, histoplasmosis and nocardiosis, are relatively uncommon. Fungal superinfection of the respiratory tract and bowel, e.g., moniliasis, may follow protracted courses of antibiotic therapy, especially in debilitated individuals.

The most common of the deep mycotic infections, clinical actinomycosis, is caused by two organisms *Actinomyces bovis* and *Nocardia*. Both produce granulomatous suppuration and a predominance of abscesses and fistulae. Clinical actinomycosis is usually a mixed infection wherein identification can be made of *Actinomyces bovis*—the anaerobic ray fungus of Wolff-Israel. Its clinical recognition lies in the observation of the sulfur granule characteristic of the fungus cluster in pus. Nocardiosis is an infection caused by a streptothrix organism, *Nocardia asteroides* being representative. True sulfur granules do not occur, but particles composed of mycelial threads and fibrin are recognizable in pus. The organisms yield an abundance of mycelial forms on culture

VIRUSES

The principal entities due to viruses encountered in surgical practice are herpes zoster, lymphopathia venereum, homologous serum jaundice and cat-scratch disease.

PROTOZOA

The principal surface infection resulting from animal parasites is caused by *Entamoeba histolytica*, the etiologic agent in amebic colitis, amebic hepatitis and abscess.

EFFECTS OF MICROBIAL INVASION

Requisites. The primary requisites for the development of infection in the body are alteration of the cellular environment and the entrance, establishment and multiplication of pathogenic bacteria in the locus. Infection may be associated with the entry of microorganisms into normally sterile tissues, as in a traumatic wound involving muscle or other deep structures, or it may be associated with conditions which support the growth of

gressive spread or beginning of localization and suppuration.

Exhaustion of pabulum, accumulation of metabolites and development of antibodies culminate in a decreased metabolic turnover and a decline in the number of microorganisms present. In pyogenic infection, a walling off and an accumulation of pus and necrotic debris result in abscess formation. At this stage, antibiotic therapy is supplementary to the release of pus and necrotic debris.

These three stages are important in the timing and response to chemotherapy. They also serve as guides for operative intervention and supportive therapy.

Usually, laboratory studies are required to confirm the etiologic diagnosis. In addition to their antibiotic sensitivities, etiologic diagnosis implies the isolation and identification of the causal microorganisms in exudate, blood (blood or bone marrow culture) or biopsy material (tuberculosis or fungal granulomas). For quick presumptive diagnosis, as in actinomycosis, infection of the urinary tract, gonorrhea or wound infection, a stained smear of the exudate may reveal, in a matter of minutes, valuable information concerning the microorganisms present. Isolation of the microorganisms and culture sensitivity tests furnish the true criteria for the selection of antimicrobial agents.

In most acute phases, reliance upon laboratory results is obviously not possible before therapy must be initiated. Once these results are obtained, the proper therapeutic measures can be adopted. Culture sensitivity tests make possible correct selection of an antibiotic or a combination of antibiotics, early recognition of mixed infection and an indication of the expected course of the disease by virtue of this knowledge of the invasiveness, toxicity and biochemical properties of the microorganisms. Present knowledge of the action of antibiotics indicates that no effect from systemic antibiotic therapy is to be expected unless the microorganisms are sensitive *in vitro*. Moderate sensitivity suggests that, if an increase in the dosage is feasible and safe, a favorable therapeutic response is possible.

Whenever deviation occurs in the expected response to therapy or when secondary infection by antibiotic-resistant organisms is suspected, antibiotic culture-sensitivity tests should be repeated. Precise laboratory diagnosis is also imperative in all staphylococcal and nonspecific infections, such as those of the urinary tract which do not respond to a

trial of empiric antibiotic therapy within forty-eight to seventy-two hours, in recurrent or metastasizing infections and in acute and chronic infections in which the surgeon is unable to determine the etiologic agent by clinical evaluation.

Errors in Diagnosis. It must be stressed that the growth of bacteria in culture does not necessarily exclude the presence of another etiologic agent or disease. Staphylococci, streptococci or other microorganisms are frequently isolated from foci which actually have as their underlying basis fungal infection, tuberculosis, a neoplasm or other lesions. Positive cultures taken from them may represent contaminants or secondary invaders. Also, in polybacterial infections such as acute secondary peritonitis, sensitivity data on aerobic organisms without accompanying anaerobic cultures may be misleading. Conversely, the report of "no growth" may or may not be valid. If inoculation on suitable media was delayed, swabs containing exudate may have dried out. If few in number, the organisms may have died in the interim. The culture media may not have been suitable and microorganisms, such as anaerobic species, may have been missed because proper culture techniques were not employed. Cultures may have been discarded before sufficient time had elapsed for the development of slow-growing organisms.

If the organisms cannot be demonstrated by repeated smear, biopsy or culture, and if microbial disease is strongly suspected, it may be necessary to resort to agglutination tests, as in typhoid fever, or to complement fixation and/or skin tests, as in tuberculosis or chancreoid. Other indirect diagnostic procedures include roentgenographic studies to test for the presence of infiltrating disease, congenital anomalies, acquired obstruction, sinuses or fistulae.

It is especially important to rule out causes of pain and fever, other than those due to infection, which are not influenced by antibiotic therapy. Among these are virus infections of the respiratory tract, liver or central nervous system or mononucleosis; nonmicrobial inflammations, such as phlebitis or infarct, cholecystitis, regional enteritis and ulcerative colitis; collagen diseases; metabolic diseases, such as thyrotoxicosis or cirrhosis and neoplasm, blood dyscrasias, lymphomas, serum sickness and drug fever.

Local Therapeutic Measures. These include (1) protection from trauma; (2)

the temperature tends to drop. As the body temperature increases, the respiratory rate and, to a lesser extent, the depth of respiration increase. The cardiac rate also increases.

Plasma and electrolyte loss may be reflected in hemoconcentration and other changes, such as reduced blood volume. The augmented excretion of nitrogenous products in the urine is evidence that protein destruction is increased. If peripheral vascular resistance is reduced to a significant degree, a sharp fall occurs in blood pressure and vasomotor collapse may occur.

The shock syndrome accompanying overwhelming infections may be due to causes other than effects on peripheral vessels. Other mechanisms which may cause shock are reduction in blood volume, direct effect of infection on the heart, adrenal insufficiency, anemia and vitamin deficiency.

COLLATERAL INFLUENCES ON THE COURSE OF INFECTION

Local Factors. The elimination of infection and institution of tissue repair are hampered when (1) the blood supply to the area is impaired, (2) blood clots, accumulations of serum, foreign bodies and devitalized tissue are present, (3) large accumulations of pus are under tension, cutting off the circulation and curtailing phagocytic activity; (4) rigid fibrotic walls are formed which impede collapse of tissue defects and sterilization of the cavity, (5) obstruction is present and impairs physiologic function of an organ such as in the bronchus, biliary tree or lower urinary tract, (6) the exposed surface wound is subject to reinfection; (7) superimposed trauma of any sort increases tissue damage still further, (8) movement delays localization and enhances the absorption of toxic products from the infected area, (9) dependent position of extremities slows resolution of edema, and (10) drainage of accumulated exudate and débridement of necrotic tissues are delayed or inadequate. The rationale of surgical treatment lies in the correction of these factors.

Systemic Factors. Certain systemic factors also influence the course of infection: (1) cardiovascular: shock, anemia, agammaglobulinemia or bone marrow suppression from any cause; (2) metabolic: starvation, uncontrolled diabetes or neoplastic cachexia; (3) hormonal: Cushing's disease, stress of major surgical procedures, and (4) therapeutic: prolonged treatment using corticosteroids, nitrogen mustard, irradiation, or

other bone marrow depressants or antibiotic therapy culminating in superinfection from alteration of the indigenous flora of the body. The rationale of supportive treatment lies in the correction of these factors.

PRINCIPLES OF TREATMENT

The basic principles of treatment of bacterial inflammations consist of early clinical and etiologic diagnosis, the institution of appropriate local and general supportive measures and specific antimicrobial therapy. Details of the application of these principles will necessarily vary with the nature and location of the infection. In general, however, some or all of them may be applied to produce a beneficial effect.

Early, Accurate Diagnosis. The diagnosis of infection is based upon the history, clinical manifestations and the identification of specific etiologic microorganisms. Little difficulty is encountered when the clinical pattern conforms to that usually associated with classical infection of the body area involved. Obstacles to accurate etiologic diagnosis present themselves when infections are atypical or when they involve deep structures such as the neck and the cavitory organs. Under such circumstances it may be necessary to call upon every appropriate diagnostic aid available.

Careful history of the illness and a physical examination may suggest the specific etiology of the infection. Microorganisms in the body develop and reproduce in a pattern roughly following their growth patterns *in vitro*.

The incubation period, or lag phase, is the interval between contamination of the tissues and the onset of infection. During this period, the reaction of the tissues to the products of bacterial metabolism has not progressed sufficiently to produce the typical local signs and symptoms of infection. Clinical manifestations during the incubation period are vague headache, malaise and fatigue. The incubation period may extend over a period of hours (hemolytic streptococcal sepsis), days (tetanus) or weeks (tuberculosis).

There is a phase of rapid, constant growth—the time of greatest microbial activity—when the organisms can be influenced most effectively by antibiotic therapy. This period is evident by the general and local clinical manifestations of inflammation—chills, fever, leukocytosis, pain, tenderness, discoloration, swelling and limitation of function. The peak of the disease is evidenced by either pro-

set up by bacteria causes destruction of tissue or is sufficiently active to produce a focus resulting in pronounced constitutional symptoms and signs. This is especially true when the active focus is in a structure not essential to the body, e.g., a congenital anomaly, the appendix, gallbladder, part of a lung, uterine tube or lymph nodes.

Whenever dead space is present, its elimination is necessary for total eradication of infection, e.g., in sinus tracts, fistulae and cavities with rigid unyielding walls, infected thyroglossal, branchiogenic, dermoid or pilonidal cysts and other foci of chronic infection.

Supportive Measures. Supportive therapy is designed to hasten the natural processes of recovery and to combat the effects of infection. The various measures employed are analgesics and antipyretics for relief of pain, fever and restlessness; administration of fluids, electrolytes, vitamins and calories to meet increased metabolic demands in addition to normal losses, transfusions of whole blood to correct anemia, blood loss or reduced blood volume; gamma globulin to correct hypogammaglobulinemia, and vasopressor drugs to combat peripheral circulatory collapse. Further, supportive therapy also includes concurrent treatment of underlying cardiovascular, metabolic or hormonal conditions.

Specific Measures. These include the administration of antitoxins, sera and antimicrobial agents. The purpose of specific therapy is to interrupt the natural course of the disease. Except for tetanus antitoxin in established tetanus, the use of vaccines, sera and antitoxins for the treatment of specific infection has been supplanted largely by specific antibiotic therapy. Vaccines and toxoids continue to be important, however, in inducing specific active immunity in the host.

PRINCIPLES OF ANTIMICROBIAL THERAPY

There are certain basic principles in utilizing antimicrobial therapy to combat infections.

The exact site of the inflammation must be localized from the history, from physical examination and from appropriate diagnostic procedures. The causative agent must be isolated and cultures for antibiotic sensitivities are to be taken whenever possible. In cases in which it is not possible to obtain cultures or in which the cultures cannot be

relied upon, the clinical syndrome must dictate empiric selection of the antibiotic.

The basic principles of management have not changed, nor is antibiotic therapy a substitute for tried and proved indications for surgical intervention. Antimicrobial therapy, however, has modified the time for application in certain situations.

Antibiotics must be given in doses sufficient to contact the causative organisms at the site of the lesion. This demands knowledge of the drug's pharmacologic and toxicologic properties and of the physiologic and pathologic barriers to its diffusion into the tissues. If no response has been noted in the usually accepted time, the indications for the use of the antibiotic should be reviewed critically.

A singly effective antibiotic is preferred whenever possible. The use of a combination of two or more antibiotics simultaneously administered separately or as a single mixed preparation should be based on bacteriologic studies showing that the infectious agent is resistant to single drugs, but susceptible to a specific combination. The principal indications for combination antimicrobial therapy are: (1) in the topical employment of nonabsorbable drugs of limited spectrum, such as polymyxin, bacitracin and neomycin, for mixed infections of skin and granulating wounds; (2) in the use of drugs with potentialities for rapid emergence of drug-resistant mutants during treatment, e.g., micrococcal infections treated with erythromycin or novobiocin and streptomycin; (3) in the treatment of desperately ill patients with suspected infections of unknown etiology, until bacteriologic studies are available, and (4) in the treatment of staphylococcal bacteremia, meningitis or pneumonia, and in gram-negative sepsis resistant to single drugs. When drugs are given in combination, full doses of each member of the pair should be given for optimal results.

Supportive therapy to bolster host resistance and correct deficits is a necessary complement to antimicrobial therapy. Steroid therapy is reserved for support of patients receiving these drugs preoperatively and for support of patients with septic bacterial shock until the lesion can be controlled by standard treatment.

The most important limitations and dangers of antimicrobial therapy are diagnostic errors; symptomatic rather than specific treatment; masking of serious infection with-

avoidance of secondary infection and superinfection; (3) heat, (4) incision and drainage, (5) débridement, (6) extirpation of infected foci, and (7) elimination of dead spaces.

Protection against trauma is provided by total body rest in serious infections and by local rest, induced by bulky compression dressings, splints, slings and adhesive strapings as in the case of extremities. Rest and immobilization also furnish protection of the lesion from additional trauma such as accidental bumping or striking of the area of infection and manipulation of the lesion by the patient or others. Gentleness during examination and changes of dressing is also a requisite as is application of bandages in such a manner that they cannot cause constriction or friction.

Protection against secondary infection implies special care during exposure of the open wound in order to avoid superinfection. It also requires avoidance of ingress of bacteria from dressings soaked through with exudate. Soaked dressings must be changed immediately.

Heat may be applied locally to increase blood flow and for comfort. The application of heat, particularly in the form of hot soaks, has been supplanted largely by dry treatment since the advent of antibiotic therapy. Objections to using hot soaks are delay of incision and drainage until skin necrosis has occurred, predisposition to swelling, tendency of sodden tissues to narrow drainage exits, possibility of satellite infections from the wet environment and of superinfections from frequent exposure of the wound, and danger of thermal injury. At present the principal use for moist heat is to loosen crusts and minute particles of devitalized tissue from the superficial dirty wound.

The purpose of incision and drainage is to provide an exit for a collection of pus and necrotic debris. Antibody, cellular and chemotherapeutic elements from the blood stream may then gain access to residual areas of infection and provide conditions for wound healing. Drainage by aspiration with a sterile needle and syringe may be employed for diagnosis and for removal of pus in situations where secondary infection or disturbance of function by incision and drainage poses a major threat. Examples are early pericarditis, pleural empyema and suppurative arthritis. The aspirations are repeated whenever exudate reaccumulates. Instillation of a solution of an appropriate

antibiotic is frequently employed in conjunction with removal of pus by aspiration. Proteolytic enzymes and irrigating fluids are used occasionally to promote drainage by thinning of exudate in such areas as sinus tracts, the pleural cavity, joints and a paralyzed urinary bladder.

The incision is made large enough to provide an adequate opening in the cavity. It is placed in such a manner that gravity drainage is obtained and, insofar as possible, it follows the lines of tension of the skin to avoid an unsightly scar or a scar that later may interfere with function of the part. In critical areas, such as the hand or the neck, care must be exercised to avoid damage to blood vessels, nerves and tendons. Culture of exudate is always taken as a precaution against any diagnostic or therapeutic error. Drainage is enhanced and maintained by the use of gauze, wicks, rubber, plastics or catheters. These drains establish a channel from the surface to the center of the cavity. If proper sterile precautions are not taken during a change of dressings, secondary infections are a frequent complication. Drains are shortened or removed as soon as it is apparent that the discharge has subsided. If drains are allowed to remain too long, a rigid-walled tract may develop and persist, in addition to the hazard of secondary infection.

A patent bronchus is a requirement in the resolution of pulmonary disease. Free flow of urine and bile and of bowel contents is also a necessity in urinary, biliary and enteric infections. Antibiotic therapy, therefore, is not fully effective when calculus obstructs the urinary tract or biliary system or when there is a subarachnoid block or a block of a secreting organ. The obstruction must be corrected before antibiotic therapy is maximally effective.

Débridement—often an accompaniment of incision and drainage—has for its purpose the elimination of harmful factors such as foreign bodies, hematomas, loculations, necrotic sloughs and abscesses in granulation tissues. Precise excision when there is a high level of antibiotics in the blood is regarded as the opportunity to eliminate the pabulum necessary for bacterial growth and, at the same time, allow the antibiotic and host defense mechanisms free access to residual bacteria on the wound.

Extirpation of foci or centers of microbial activity is a specialized form of débridement. It is advantageous to extirpate the local focus whenever the inflammatory process

HOST-PARASITE RELATIONSHIPS

Antimicrobial drugs may alter these relationships in the tissue response, in the immunologic response and in the bacterial flora indigenous to the body.

Alterations of Tissue Response. Whereas chemotherapy is aimed at sterilization of the infective process—a goal rarely achieved—recovery can only be obtained by means of the defense mechanisms of the body. Antibiotic action may injure the infecting agent sufficiently to alter its invasiveness or to reduce its ability to produce harmful substances. When the number of organisms is kept to a minimum by an antimicrobial agent, a lower level of resistance of the host may be effective in checking spread of infection and promoting recovery. There is no convincing evidence, however, that chemotherapy inactivates the toxic metabolites of bacteria after they have formed and entered the general circulation. Consequently, in order to minimize the effects of the infection, large accumulations of pus must still be drained, antitoxin must be administered for clinical tetanus, hopelessly damaged muscle must be removed promptly in gas gangrene and circulation must be supported in vascular collapse due to gram-negative bacillary endotoxemia. When indicated, general measures must also be instituted to bolster the body defenses.

The tissue response may also be modified under circumstances in which the drug suppresses multiplication of microorganisms but does not eradicate them. With bacteriostatic drug therapy only temporary response may occur in diseases such as acute osteomyelitis, pyelonephritis, staphylococcal empyema and subacute bacterial endocarditis. In this way, an acute infection may be converted to a chronic one.

Alterations of Immunologic Response. As the intensity and duration of therapy are modified by antibiotic therapy, the immunologic response of the host may also be modified. This alteration is of no serious consequence in many acute bacterial inflammations, but in others it may be. For example, in typhoid fever chloramphenicol may greatly accelerate recovery, but a relapse may occur in some patients as soon as the drug is withdrawn. At times an alteration of the immunologic response may be desirable. For example, infection with beta hemolytic streptococci is often followed by the development of antistreptolysin antibodies and, occasionally, by the development of rheumatic fever. If the infective process can be

interrupted early and completely by a bactericidal drug such as penicillin, the development of antibodies and of rheumatic fever can be prevented, presumably by interference with host reactions.

Alteration of Microbial Flora. Blood-borne antibiotics have an effect not only on microorganisms of the infectious process, but also on members of the bacterial flora of the body wherever they reside. Drug-susceptible members of the normal flora are suppressed and an imbalance is created which may in itself lead to disease—superinfection. Patients are especially vulnerable to superinfections who have lowered resistance associated with anatomic defects, cachexia from any cause, blood dyscrasias and hormonal or metabolic disturbances.

In debilitated patients, the bacterial flora of the nasopharynx is suppressed, allowing resistant staphylococci, coliform bacilli and yeasts to multiply freely; these resistant forms occasionally cause thrush, pneumonia or septicemia. In women taking large oral doses of a broad-spectrum antibiotic, the normal vaginal flora may be suppressed permitting marked overgrowth of yeasts; this leads to moniliasis. In postoperative patients, in whom alimentation by mouth is interrupted for a few days, suppression of fecal flora may lead to overgrowth of staphylococci and to staphylococcal enteritis.

Disturbances in normal microbial flora can give rise to secondary disorders other than superinfection. Nutritional deficiencies may occur when the normal intestinal flora is suppressed for a long time. Bleeding may develop because of a deficiency of vitamin K that is normally synthesized in part by the intestinal flora.

HOST-DRUG RELATIONSHIPS

The condition of a patient governs the route of administration and choice of antibiotic. Coma, paralytic ileus and vomiting are examples of conditions which may preclude the oral route of administration except by gavage. The inability of certain antibiotics, such as bacitracin, polymyxin, kanamycin, neomycin and streptomycin to be absorbed into the general circulation after oral administration precludes oral use of these drugs except for intra-enteric action. Peripheral circulatory collapse or other cause of interference with absorption of a drug from the upper gastrointestinal tract is also a contraindication for oral antibiotic therapy. Under such circumstances, intramuscular or intravenous therapy is necessary to

DRUG-PARASITE RELATIONSHIPS

It has been noted that, *in vitro*, we are dealing with rapidly proliferating microorganisms in continuous contact with a known concentration of drug in a culture medium of fixed composition. In the body, environmental factors and concentrations of antibiotics vary widely.

Antibiotic therapy is optimally effective in early, acute microbial inflammations. Most bacteria responsible for invasive infections are extracellular in location and are readily accessible to phagocyte cells and antimicrobial drugs. As the lesion progresses, the bacteria in the periphery of the lesion continue to proliferate rapidly while those in the center of the focus, finding less suitable conditions for growth, multiply less rapidly and are less susceptible to drug action. Dormant, or slowly metabolizing, organisms thus may survive high concentrations of antibiotic and, subsequently, may produce a clinical relapse of infection.

Diffusion of Antibiotics. The longer the infection persists, the less likely is the possibility of a blood-borne drug reaching the infected tissues in therapeutic concentrations. The lesion induced by the microorganism actually may "protect" it from the drug. The walls of an abscess, for example, are relatively avascular and may form a partially obstructive barrier to drugs and body defense mechanisms. Fibrin deposits, if dense enough, may also impede free diffusion of an antibiotic, whereas frank pus and necrotic tissue may adsorb a drug and thus prevent its distribution to bacteria. Once bacteria become located within tissue cells, the cell membrane may protect them from drug activity. Some drugs, for example isoniazid, reach about the same concentration in monocytes as in the extracellular fluid. With

to be facilitated by the reaction of inflammation. Diffusion from blood into acute inflammations in bone, the pleural cavity, the tracheobronchial tree, the brain and the meninges results in local tissue and exudate levels which are lower than those obtained in blood serum. This handicap is overcome by increasing the total daily dose of antibiotic and by supplemental topical application where feasible.

The tetracyclines and chloramphenicol reach the brain in therapeutic concentrations via the blood stream, but penicillin, streptomycin and erythromycin do not. In the meninges, sulfadiazine and chloramphenicol diffuse readily from the blood, whereas diffusion of penicillin and the tetracyclines is slight unless acute inflammation is present. Parenterally administered sulfadiazine, penicillin and erythromycin can be detected in pancreatic secretions, but not the tetracyclines, chloramphenicol, bacitracin or polymyxin. The tetracyclines and erythromycin can be assayed in therapeutic concentrations in the prostate and prostatic secretions, whereas only a trace of penicillin, streptomycin and chloramphenicol may be found when optimal blood serum levels are present. The internal compartments of the eye are barred from blood-borne antibiotics with the exception of chloramphenicol.

Topical Therapy. Topical therapy, in addition to or in place of parenteral therapy, may be of value for the localized lesion. The principal indications for topical therapy are (1) accessible *Pseudomonas* infections, as in external otitis (polymyxin), (2) proved monilial infections (nystatin), (3) superficial infections caused by microorganisms sensitive *in vitro* to the antibiotic employed, e.g., infected granulating surfaces, and (4) infections in regions of the body difficult to reach by blood-borne drugs. Good nursing care of the lesion is an important concomitant of topical therapy.

The requisites for successful topical therapy are absence of necrotic tissue, susceptibility of the organisms to the antibacterial agent, use of an agent that is neither allergenic nor toxic to the tissue cells, constant and adequate contact between the site of the infection and the drug and prevention of recontamination of the wound with resistant organisms by a rigid aseptic technique in wound management. Bacitracin, neomycin, polymyxin, chloramphenicol and the tetracycline antibiotics are preferred for local therapy because they are usually well tolerated when so administered.

Distribution. The focus of infection is a complex one and may result in significant interference with drug action.

The distribution of drugs varies greatly in different tissues. Some antibiotics delivered by the blood stream reach certain internal organs and others do not. In the absence of large accumulations of pus, parenterally administered antibiotics are effective against acute infections involving soft tissues, lung parenchyma, biliary tree, peritoneal cavity and urinary tract. Diffusion of the drugs from blood serum into these tissues appears

HOST-PARASITE RELATIONSHIPS

Antimicrobial drugs may alter these relationships in the tissue response, in the immunologic response and in the bacterial flora indigenous to the body.

Alterations of Tissue Response. Whereas chemotherapy is aimed at sterilization of the infective process—a goal rarely achieved—recovery can only be obtained by means of the defense mechanisms of the body. Antibiotic action may injure the infecting agent sufficiently to alter its invasiveness or to reduce its ability to produce harmful substances. When the number of organisms is kept to a minimum by an antimicrobial agent, a lower level of resistance of the host may be effective in checking spread of infection and promoting recovery. There is no convincing evidence, however, that chemotherapy inactivates the toxic metabolites of bacteria after they have formed and entered the general circulation. Consequently, in order to minimize the effects of the infection, large accumulations of pus must still be drained, antitoxin must be administered for clinical tetanus, hopelessly damaged muscle must be removed promptly in gas gangrene and circulation must be supported in vascular collapse due to gram-negative bacillary endotoxemia. When indicated, general measures must also be instituted to bolster the body defenses.

The tissue response may also be modified under circumstances in which the drug suppresses multiplication of microorganisms but does not eradicate them. With bacteriostatic drug therapy only temporary response may occur in diseases such as acute osteomyelitis, pyelonephritis, staphylococcal empyema and subacute bacterial endocarditis. In this way, an acute infection may be converted to a chronic one.

Alterations of Immunologic Response. As the intensity and duration of therapy are modified by antibiotic therapy, the immunologic response of the host may also be modified. This alteration is of no serious consequence in many acute bacterial inflammations, but in others it may be. For example, in typhoid fever chloramphenicol may greatly accelerate recovery, but a relapse may occur in some patients as soon as the drug is withdrawn. At times an alteration of the immunologic response may be desirable. For example, infection with beta hemolytic streptococci is often followed by the development of antistreptolysin antibodies and, occasionally, by the development of rheumatic fever. If the infective process can be

interrupted early and completely by a bactericidal drug such as penicillin, the development of antibodies and of rheumatic fever can be prevented, presumably by interference with host reactions.

Alteration of Microbial Flora. Blood-borne antibiotics have an effect not only on microorganisms of the infectious process, but also on members of the bacterial flora of the body wherever they reside. Drug-susceptible members of the normal flora are suppressed and an imbalance is created which may in itself lead to disease—superinfection. Patients are especially vulnerable to superinfections who have lowered resistance associated with anatomic defects, cachexia from any cause, blood dyscrasias and hormonal or metabolic disturbances.

In women taking large oral doses of a broad-spectrum antibiotic, the normal vaginal flora may be suppressed permitting marked overgrowth of yeasts, this leads to moniliasis. In postoperative patients, in whom alimentation by mouth is interrupted for a few days, suppression of fecal flora may lead to overgrowth of staphylococci and to staphylococcal enteritis.

Disturbances in normal microbial flora can give rise to secondary disorders other than superinfection. Nutritional deficiencies may occur when the normal intestinal flora is suppressed for a long time. Bleeding may develop because of a deficiency of vitamin K that is normally synthesized in part by the intestinal flora.

HOST-DRUG RELATIONSHIPS

The condition of a patient governs the route of administration and choice of antibiotic. Coma, paralytic ileus and vomiting are examples of conditions which may preclude the oral route of administration except by gavage. The inability of certain antibiotics, such as bacitracin, polymyxin, kanamycin, neomycin and streptomycin to be absorbed into the general circulation after oral administration precludes oral use of these drugs except for intra-enteric action. Peripheral circulatory collapse or other cause of interference with absorption of a drug from the upper gastrointestinal tract is also a contraindication for oral antibiotic therapy. Under such circumstances, intramuscular or intravenous therapy is necessary to

insure blood-borne delivery of therapeutic concentrations of the drug.

In some patients the administration of antibiotics may be attended by harmful effects. They may be classified into complications caused by sensitization and direct toxic effects. These effects may be manifested with the first dose of the drug and are known as idiosyncrasies. However, toxic symptoms usually do not appear until the patient has been receiving drug therapy for several days. Direct drug toxicities are associated with the use of large doses of a particular drug, prolonged courses of therapy, frequent repetition of short courses or topical applications.

The toxic manifestations of the various antibiotics are listed in Table 1

ANTIBIOTICS AND THEIR IMPORTANCE IN SURGICAL INFECTIONS

Practically all of the antibiotics are available in three dosage forms, tablets or capsules for oral administration, vials of the sterile drug to be used in solutions for intramuscular, intravenous and local injections, and topical preparations in the form of dry powders, ointments, lotions and solutions. Confusion often occurs because of the various proprietary names that different manufacturers have given to the same antibiotic. Therefore, the physician should be familiar with the generic name of every preparation.

Penicillin. One of the first of the antibiotics, penicillin, has been and still is potentially the most useful of all of the

antimicrobial agents. Group A hemolytic streptococcal infections, peritonitis, osteomyelitis, pneumococcal pneumonia, syphilis, gonorrhea, anthrax, gas gangrene and Wolff-Israel actinomycosis are indications for penicillin therapy. This antibiotic is highly effective against staphylococcal infections when the organisms are penicillin sensitive. Penicillin is the drug of choice for prophylaxis against impending hemolytic streptococcal and toxigenic clostridial infections.

The dosage form and amount of the drug to be given depend entirely on the sensitivity of the organism and the nature and location of the lesion. Penicillin G, 250 mg given orally every four hours, alone or with probenecid (Benemid) administered concurrently to blockade renal secretion of the drug, is adequate for streptococcal infections in circumstances where intramuscular penicillin therapy is undesirable. For intramuscular therapy, there is a choice between solutions of aqueous penicillin G to produce especially high, but short-lived, blood levels, and repository or depot forms, such as procaine penicillin G in aqueous solution to produce lower therapeutic blood serum levels for a period in excess of twelve hours. Intravenous drip of an aqueous penicillin G solution produces a high and more or less constant blood level.

Unfortunately, the general application of penicillin for susceptible infections has been curtailed because a significant number of patients have become sensitized to the drug. It was mentioned previously that penicillin

Table 1. Toxic Reactions of Antimicrobial Agents

PENICILLIN G	Allergic Reactions rashes, eruptions, serum sickness-like reactions, exfoliative dermatitis, anaphylactic shock, contact dermatitis
STREPTOMYCINS	Rashes, contact dermatitis, vertigo (streptomycin), deafness (dihydrostreptomycin), drug fever, eosinophilia, transient cylindruria
CHLORAMPHENICOL	Skin eruptions—rare, aplastic anemia, others as under tetracyclines
TETRACYCLINES	Skin eruptions—rare, vomiting, diarrhea, stomatitis, glossitis, proctitis, enterocolitis, superinfection from overgrowth of resistant organisms (Staphylococci, Monilia, Pseudomonas, Proteus), thrombophlebitis after intravenous administration
ERYTHROMYCIN AND OLEANDOMYCINS	Nausea, vomiting, diarrhea
NOVOBIOCIN	Skin eruptions; eosinophilia, granulopenia, yellow plasma
RISTOCETIN	Skin eruptions, diarrhea, drug fever, neutropenia
VANCOMYCIN	Skin eruptions, phlebitis, Intravenous route, fever
NEOMYCIN AND KANAMYCIN	Topical—harmless, except in peritoneal cavity, apnea, respiratory arrest from overdosage in anesthetized patients (neomycin) Oral—loose stools Injection site—pain. Parenteral—deafness, nephrotoxicity
POLYMYXIN	Topical—harmless, rashes rare, injection site, pain; headache, hypesthesias, fever, transient albuminuria; cylindruria
BACITRACIN	Topical—harmless; rashes rare, injection site, pain, transient nephrotoxicity

also has a diminishing sphere of influence in staphylococcal infections because of the growing prevalence of resistant strains.

A search for drugs effective against staphylococci resistant to penicillin and other antibiotics has led to the discovery of bacitracin, erythromycin, oleandomycin, ristocetin, novobiocin, vancomycin and kanamycin. Other antibiotics will undoubtedly be discovered and added to this list. These antimicrococcal drugs usually show no cross-resistance when used with the major antibiotics. Their action may be bacteriostatic (erythromycin, oleandomycin, novobiocin) or bactericidal (bacitracin, vancomycin, kanamycin). It is preferable to give erythromycin and novobiocin orally, whereas kanamycin, vancomycin and bacitracin must be administered by injection, except when used for intra-enteric infections, such as staphylococcal diarrhea, because of failure of absorption from the bowel. Bacitracin is especially useful for topical therapy of pyogenic infections because of its low allergenic potential.

Streptomycin. This drug is bactericidal for gram-negative and gram-positive bacteria, including tubercle bacilli. Both gram-positive and gram-negative organisms commonly have mutants which are resistant to high concentrations of streptomycin. These may emerge after three to five days of streptomycin therapy and supplant previous susceptible flora unless all infecting bacteria have been destroyed during that interval. For this reason, streptomycin is usually employed in combination with another drug to which the organisms are also susceptible.

At present there are four sets of circumstances indicating systemic streptomycin therapy: (1) in tuberculosis, therapy being supplemented by another antitubercular drug such as isoniazid or para-aminosalicylic acid, (2) in subacute bacterial endocarditis, adding penicillin; (3) in secondary bacterial peritonitis, also using penicillin, and (4) in miscellaneous gram-negative bacillary infections. Among the more important of the latter are bacteremia, urinary tract infections and meningitis. Streptomycin is given intramuscularly in doses of 2 to 3 gm. a day for acute nontuberculous infections and it is administered in divided doses at six-hour intervals. The dosage in tuberculosis is 1 gm given three times a week. The problem posed by the development of streptomycin-resistant strains in the treatment of tuberculosis has led to a continuing search for antitubercular agents.

Neomycin. The antimicrobial spectrum is essentially the same as of streptomycin, but with only selective cross-resistance. However, nephrotoxicity and ototoxicity have confined its uses primarily to oral and topical administration. It is sometimes used intramuscularly in divided doses of 0.75 gm. a day in life-endangering gram-negative sepsis which is completely resistant to other agents, particularly that due to *Proteus* and *Aerobacter*. Principal indications by mouth are for preoperative suppression of the intestinal flora; for treatment of staphylococcal enteritis; for treatment of impending hepatic coma in which intestinal ammonia-producing organisms contribute to toxemia; for aerosol therapy of chronic bronchial suppuration, and for local therapy of infected granulating wounds.

Kanamycin has essentially the same spectrum of activity and clinical applications as neomycin.

The Tetracyclines. Tetracycline and its two analogues chlortetracycline (Aureomycin) and oxytetracycline (Terramycin) are almost identical: (1) in their wide range of antimicrobial activity extending to the rickettsial species and including gram-positive and gram-negative bacteria; (2) in the fact that the three agents give almost complete cross-resistance (if a microbial strain is resistant to one of the three drugs, it is usually resistant to all), and (3) in the pattern of side effects incident to therapeutic use. In hospitals, staphylococci and species of *Proteus* and *Pseudomonas* are frequently resistant and resistant coliform bacteria are encountered with increasing frequency from widespread use of these antibiotics. The principal untoward effects of tetracycline therapy are gastrointestinal upsets and replacement of indigenous bacterial flora with drug-resistant species with impending superinfection. Therefore, caution is necessary when a tetracycline drug is prescribed prophylactically and for minor pyogenic infections or chronic suppurations of the respiratory tract. The principal indications for tetracycline in surgical practice are: (1) infections of the liver and biliary system, (2) peritonitis, diverticulitis and amebic colitis, (3) pyogenic infections in patients who are allergic to penicillin; (4) gram-negative bacillary infections of the urinary tract, and (5) other infections in which the causative organisms are sensitive to tetracycline but are not to other antibiotics. The usual adult dosage of tetracycline administered orally or intravenously is 1.0 to 1.5 gm. a day in two

or three equal, divided doses. The addition of certain excipients (citric acid, glucosamine) to capsules containing tetracycline enhances absorption of drug from the gastrointestinal tract into the blood stream. Following absorption, high concentrations of the drug can be recovered in bile, stools, urine and peritoneal fluid. Wherever superinfection with monilia is a serious threat, tetracycline may be given concurrently with the antimonilial drug, Mycostatin. This antifungal agent is also used alone in doses of 500,000 units four times a day for monilial infections of mouth, bowel or vagina.

Chloramphenicol. This antibiotic, produced by chemical synthesis, has about the same spectrum of effectiveness as the tetracyclines, but it produces only a slight cross-resistance with them. Thus, tetracycline-resistant organisms often remain chloramphenicol sensitive. The toxicity of this drug for the hematopoietic system has been greatly exaggerated. In the rare instances when toxicity occurs, it follows protracted usage and heavy doses, often with repeated courses, for such conditions as chronic bronchiectasis or chronic urinary tract infection. In children, however, it may follow treatment for five or more days of such acute infections as nonspecific upper respiratory tract infections, whooping cough and gastroenteritis. The principal indications for chloramphenicol therapy are: (1) staphylococcal, gram-negative bacillary or mixed infections resistant to other antibiotics but sensitive to chloramphenicol, (2) typhoid fever, (3) pyogenic infections of the central nervous system, and (4) pyogenic infections of the eye. The usual dosage regimen for adults is an initial "loading" dose of 1 gm given orally and followed by 0.5 gm at four- to six- or eight-hour intervals, depending on the severity of the infection.

Polymyxin B. Polymyxin B, a basic polypeptide, is rapidly bactericidal for many species of gram-negative bacteria and is the most uniformly effective of all the known antibiotics in treating infections due to *Pseudomonas*. It exerts no action on *Proteus* or the gram-positive bacteria. Polymyxin produces unpleasant, but usually harmless, neurotoxic effects in some patients (paresthesias, dizziness) and is somewhat nephrotoxic, particularly in individuals having impaired renal function. Therefore, the daily dose must not exceed 20 mg. per kg. per day in divided doses, injected intramuscularly, for not more than ten days. Pain and swell-

ing at the site of injection are minimized by dissolving the drug in a solution of a local anesthetic agent. The principal indications for systemic polymyxin therapy are gram-negative bacteremia and severe urinary tract infections, especially those due to *Pseudomonas*, and for mixed infections, when used with tetracycline or chloramphenicol. The large molecular size of the drug prevents good diffusion and penetration in cerebrospinal and pleural fluids and in relatively avascular tissues. *Pseudomonas meningitis* has been treated by direct intrathecal injections of small doses of polymyxin with no ill effects. Topical application of polymyxin alone, or in combination with neomycin or bacitracin, is useful for surface infection because of low allergenic potential.

PREVENTION AND CONTROL OF NEW INFECTIONS ACQUIRED IN HOSPITALS

Control of infection in the hospital population is a continuing problem. To keep the incidence of acquired infections to an absolute minimum is of paramount concern to all Staphylococci and the various gram-negative bacilli are most commonly the causal organisms, and they are frequently multi-antibiotic resistant. These bacteria are especially important risks for those with reduced general or local tissue resistance. The primary reservoirs of these bacteria are acute and chronic suppurations and asymptomatic carriers. Secondary reservoirs include all hospital equipment as well as clothing. A number of surveys have revealed that infection rates in hospitals using antibiotics routinely as the first line of defense against infection are higher than in those not doing so. It has been shown also that rigid application by all concerned of clean and aseptic techniques in operating rooms and wards and in the treatment of established infections is effective in reducing the incidence of acquired infections among patients, staff members and personnel. The fundamental approaches, therefore, are two: (1) reduction of the incidence of resistant bacteria, and (2) reduction and prevention of cross-infections by these bacteria.

Reduction in the Prevalence of Drug-Resistant Bacteria. As stated previously, a fundamental principle of antibiotic therapy is restricting their use to conditions in which they have been proved effective. Administration of antibiotics for prophylaxis now outnumbers prescriptions for therapy of in-

fection. The accepted indications for prophylactic antibiotic therapy are much more limited than generally practiced.

The limiting factors in antibiotic prophylaxis are these: (1) the drug must be chosen in the absence of bacteriologic data; (2) no antibiotic is universally effective against all potential invaders; (3) the wound environment—tissue necrosis, hematomas, foreign bodies—may inhibit the effectiveness, and (4) the nature of the lesion may prevent contact between blood-borne drug and bacteria.

The principal indications for prophylactic antibiotic therapy are prevention of hemolytic streptococcal infection and control of bacterial invasion in contaminated mechanical injuries and in operations on structures of the body which naturally harbor a large population of bacteria.

Antibiotic prophylaxis against pyogenic infection is probably of value in elective surgery in: (1) preventing further attacks in patients with rheumatic fever, (2) preventing subacute bacterial endocarditis in patients with valvular heart disease or congenital heart disease undergoing surgery in a contaminated field, (3) infants with congenital anomalies, (4) presence of chronic obstructive emphysema and (5) patients receiving prolonged high dosage steroid therapy.

Antibiotic prophylaxis is also probably warranted in delayed or nonoperative treatment of acute pancreatitis, bleeding esophageal varices, acute diverticulitis and perforated peptic ulcer or gastrointestinal carcinoma.

Traumatic Wounds Wounds of soft tissues do not become infected, or infection is trivial and wound healing uncomplicated, when such injuries are subjected to early, precise definitive surgery. It follows that antibiotic therapy is not justifiable for every bruised or lacerated wound. It is justifiable when operative management is inadequate or delayed beyond two to four hours, when the danger of invasive infection already exists and when casualties have sustained penetrating wounds of the joints or the major body cavities which extend into structures harboring resident bacterial flora.

Penicillin is probably the safest and most tested antibiotic today, although cases of hypersensitivity may preclude its use and call for the substitution of another antibiotic. Therapy is instituted at the time of definitive surgery and it is continued postoperatively for three to five days. Immunization against tetanus is also effected.

Thermal Injuries. The burn wound requires special consideration. The magnitude of the injury often involves extensive areas of the body surface. Surgical excision and closure by skin graft are sometimes difficult, if not impossible, because of frequent inability to diagnose accurately the depth of the burn on first inspection and because secondary infection threatens until complete healing is achieved. The rationale for antimicrobial therapy in the burned patient is demonstrated by the rare instances of death from hemolytic streptococcal septicemia since its institution.

As in other traumatic wounds, chemoprophylaxis is but one factor in the total problem of prevention of wound suppuration in the burn eschar.

Antimicrobial therapy, therefore, seems justified only when: (1) the total area of partial and full-thickness burn involves 15 to 20 per cent or more of the body surface; (2) an associated complex injury increases the hazard of infection, (3) the patient has concurrent respiratory tract, genitourinary, or other pyogenic infection remote from the burn; (4) the patient is exposed to radiation or to steroid therapy, and (5) extensive debridement and skin grafting are carried out.

Surgical Procedures in Contaminated Fields. In elective surgery the healing process is not disturbed to as great a degree as in the traumatic or thermal wound. The danger of bacterial dissemination is also lessened by careful preoperative management. In contaminated fields the principles of prophylactic antibiotic therapy are emphasis on preoperative reduction of the regional bacterial flora by mechanical cleansing and adjunctive antibiotic therapy, the choice of antibiotic tailored to the bacterial flora of the region; and prevention of seeding contiguous tissues by proper quarantine. Postoperatively antibiotic therapy is seldom necessary unless spillage has occurred. The following are examples of contaminated cases in which antibiotic prophylaxis may be warranted:

Head and neck. Plastic operations involving the oral cavity; radical surgery for fungating carcinoma of the oral cavity and neck; esophageal diverticulum.

Thoracic. Presence of infection in the lesion cannot be ruled out preoperatively; surgery extends across potentially infected lung, mediastinal structures or esophagus; bronchopleural or tracheoesophageal fistula; cardiac or peripheral vascular surgery.

Abdominal. Transduodenal choledocholithotomy; plastic repair of bile ducts; portacaval shunt for impending hepatic coma, pancreatic or enteric fistula; regional enteritis with fistula; colon resection for inflammatory disease, strangulation, obstruction, perforation, carcinoma and after spillage during anastomosis, closure of colostomy; anoplasty with primary closure of wound, evisceration of laparotomy wound.

Obstetric and gynecologic. Premature rupture of membranes, prolonged labor; rectovaginal fistula, transplantation of ureters to bowel, pelvic organ eventeration

Genitourinary. Presence of severe urinary infection, valvular heart disease, extreme debilitation, contamination of dead space, postoperative extravasation of urine, ureteroplasty, transplantation of ureters

Surgical Procedures in "Clean" Operative Fields. A number of recent studies have shown that in patients given antibiotics there was an increased rather than decreased rate of "clean" wound sepsis. Following abolishment of routine prophylaxis and institution of a rigid program to prevent cross-contamination, the infection rate returned to the low level of the preantibiotic era. Obviously, chemoprophylaxis should be abandoned if there is no evidence that it is effective and if there are potentialities for harm.

Postoperatively antibiotic therapy is not warranted for unexplained fever, heart failure, cerebrovascular accident, atelectasis, thrombophlebitis or tracheostomy.

Reduction of Spread and Persistence of Drug-Resistant Bacteria. The ultimate success in preventing wound infection will depend upon concerted efforts to decrease exposure within the hospital environment. Infection arises within the operating room or on the wards.

Even under the most favorable conditions all wounds are contaminated at operation and whether or not infection supervenes depends as much on precise, deft surgical technique as on any other factor. Infection will seldom arise in wounds which are handled gently and closed without foreign bodies or excess necrotic tissue. Measures, other than surgical techniques which require constant checking, are those which apply to inoculations of the wound by bacteria from the air and by contact. The checks to reduce these hazards include (1) periodic check on sterilizing equipment to insure sterile instruments, gloves, solutions and textiles, (2) careful preparation of the hands and forearms of the operating team as well as of

operative fields; (3) prompt change of a punctured glove or wet gown; (4) adequate masking with a change of mask after each case, (5) avoidance of unnecessary conversation during surgery, (6) removal from duty of all personnel who harbor any open infection, (7) reduction of traffic within the operating room to a minimum, and (8) prohibition of street clothing within the operating pavilion, with similar regulations against the wearing of operating room attire for ward rounds.

Since hospital personnel are carriers of staphylococci, they should protect wounds from contact infection by the wearing of masks and the employment of an all-instrument or sterile glove technique, or both, for changes of dressings in septic cases, with washing of hands before and after each dressing. In addition, for the patient with a suppurating lesion, segregation of the wound and not necessarily the patient should be the prevailing practice. One of the main causes of wound infection is carry-over of infected discharges from one patient to another by members of the medical or nursing staff.

Physicians and attendants must be trained to realize that the bare hands must be considered dirty at all times. Once dirty bandages and dressing have been touched, the hands must be washed before the wound is treated. To avoid contamination the hands of the dresser should never touch the wound or surrounding skin area which has also been covered by dressings. The inner dressings are removed with sterile hemostats. These and other necessary sterile articles are provided for the dresser on a sterile towel. The latter then serves as the work area. The dresser never touches the reapplied dressings with his hands. Between dressings the hands are again scrubbed or washed with hexachlorophene.

In order to prevent dissemination of infected discharges, the used dressings are discarded in several thicknesses of old newspaper or in waxed-paper bags and promptly incinerated. Contaminated instruments are then dropped by the dresser into a vessel containing germicidal solution. Dressings are changed only as necessary, as frequent changes enhance the opportunity for contamination. It is well to remember the World War II adage that "inspection means infection."

Dressings should be bulky and occlusive enough to avoid soaking through, when this happens it should be considered an emer-

gency cause for redressing Patients who can do so should be encouraged to take total baths with a germicidal soap such as hexachlorophene as soon as wound healing is not jeopardized. When a wound is drained surgically, it should be covered with an occlusive dressing to prevent secondary contamination through soaked or soiled dressings. Since bacteria from the external environment readily penetrate moist gauze, especially if soaked with serum, open wounds receiving wet therapy should have waterproof (external) dressings.

For those who cannot be prevented from contaminating their surroundings heavily (extensively burned infected patients, those with generalized skin infections, tracheostomies), a reasonable regimen of isolation should be instituted. The room or cubicle contents should be treated as heavily contaminated. Needless to say, quarantine is effective and can succeed only when it is complete.

Once infection in a wound is established there is a tendency to rely on antibiotic therapy—which is usually ineffective—rather than prompt surgical intervention. There is a reluctance also among surgeons to make incisions of adequate extent to ensure proper drainage. This tendency to use small incisions which afford inadequate drainage allows puddling of pus and bacteria and causes undermining and imprisonment of the necrotic tissue upon which bacteria thrive. Invasion progresses in the depths of the tissues, masked by overlying intact skin that in itself affords no tensile strength to the wound. If the infection is allowed to progress unrecognized and undrained until bacterial invasion destroys fascia, disruption and/or evisceration are imminent. To depend on antibiotics to abort an established invasive wound infection and to treat it by conservative drainage through a small incision are conducive to dehiscence rather than insurance against it. Advent of the antibiotics has not obviated the necessity for applying the principle of surgical drainage once an infection has become established. Such conservative treatment frequently leads to prolonged hospitalization, many painful dressings, protein depletion and the subsequent development of hernias. The treatment for the established wound sepsis is early, adequate, dependent drainage before invasion of tissue and fascia has occurred.

When drainage is secured, the wound also must be rid of necrotic tissue. The protective action of appropriate blood-borne

antibiotics allows the surgical débridement of all involved tissue without fear of aggravating the process or causing extension of the invasion. Usually twenty-four to forty-eight hours of systemic antibiotic therapy will control the invasive component (cellulitis) and allow adequate débridement at the time of drainage. The surgeon is now confronted with an open clean wound, the treatment of which is surgical closure, either by suturing or skin grafting. Such wounds will heal by second intention if kept clean, but the process is prolonged and results in excessive scar formation.

BASIC PRINCIPLES OF TECHNIQUE IN SURGICAL CARE

By FRANKLIN LOUNSBURY, M.D.

FRANKLIN LOUNSBURY is the son of a surgeon and received his education at the University of Wisconsin and Northwestern University. Dr. Lounsbury is an Assistant Professor of Surgery at Northwestern University Medical School. He is particularly suited to describe procedures about which residents and interns are often in doubt. One may be well versed in the principles of the care of catastrophic surgical situations and yet be quite ignorant of the meticulous methods which, when applied promptly and judiciously, prevent the crippling complications which too often follow an apparently simple surgical lesion.

EMERGENCY ROOM PROCEDURES

Every member of the house staff in the average general hospital is certain at some time during his career to face a desperate situation in the emergency room. The life of a critically ill or injured patient may depend upon his accurate and quick appraisal of the patient's problems and rapid institution of therapy.

Examination of the Patient. An emergency examination of necessity must be rapid and not so detailed as the more leisurely routine through which the doctor takes an office patient or a hospitalized but not acutely ill patient. However, it must be searching in nature and should disclose within a matter of moments the essential pathology. The presence of a bystander who witnessed the patient's accident, or of a relative who is familiar with the patient's medical history, should help the examiner in his

search for pertinent historical data, but this information must not be obtained at the expense of the examination of the patient.

When the examiner is feeling the pulse he can observe the character of respiration. If the patient is in coma, and particularly if he is having labored respiration, the examiner must satisfy himself that there is no obstruction of the airway. The tongue should be pulled forward, and if this does not relieve respiration it may be that the patient has already aspirated mucus. The chest should be auscultated for breath sounds to see whether the air is actually getting through into the lungs. If there is any doubt, the trachea should be aspirated with a small-caliber catheter attached to a suction apparatus. In the conscious patient, continuing difficulty in respiration with cyanosis should suggest the possibility of tension pneumothorax, cardiac failure, a suck-

ing wound of the chest or some other acute process changing the intrathoracic physiology. If a determination of the pulse has established that the patient is not in cardiac arrest or in severe cardiovascular collapse, the remainder of the examination can be carried out and the information about the cardiac status mentally fitted into the rest of the picture assembled by the continuing examination.

After the pulse and respiration have been checked the head is examined. It is possible to palpate the cranium quickly and thoroughly in a matter of moments in a search for lacerations, contusions and swelling. One should look particularly for fluid issuing from the nose or ears. The size and regularity of the pupils should be noted, as well as any facial asymmetry appearing on simple examination. The cervical spinous processes posteriorly and the trachea and thyroid cartilages anteriorly can be gently but easily palpated for evidence of asymmetry. In almost the same gesture the neck can be palpated for evidence of crepitation.

The chest should then be examined carefully for evidence of wounds and a series of respiratory excursions should be watched. Breath sounds should be listened for on each side of the chest in representative areas and the heart tones should be briefly noted in the significant areas at apex and base. The examining finger can be run lightly but quickly over the rib cage on each side for evidence of rib fracture or subcutaneous emphysema. As the examination is carried posteriorly, the scapulae should be felt on each side and then, anteriorly, the clavicles. As the examiner's hands are passed laterally along the clavicle, a gross survey of the structures around the shoulder joints can be easily made. At this point both upper extremities should be quickly and deftly palpated for gross evidence of a fracture by moving the humerus about its articulation with the clavicle and scapula, and subsequently moving the forearm on the arm at the elbow in extension and flexion as well as in supination and pronation.

The patient's hands should be moved in all possible directions at the wrist. Most fractures involving the bones of the hand are apparent in the slight deformity or asymmetry produced in the area of the fracture. Thus, a fracture of the fifth metacarpal, unless it is impacted in good position, will produce a shortening of the fifth finger as the fingers are bent into the palm and will obscure the normal protrusion at the end of

the fifth metacarpal. If the patient is conscious, he should be asked to make some of the movements of the hand which would indicate involvement of the median, ulnar or radial nerves. These movements are apposition of the thumb, or tip of the thumb, to tip of the little finger, as a check for median nerve function; extension of the hand at the wrist, or the thumb at the metacarpophalangeal joint, as a test of radial nerve function, and the ability to make a cone with the fingers and thumb as indication of ulnar nerve function.

If the patient is unconscious, weakness or paralysis of the upper extremity can be determined by raising the patient's arm passively above his face and allowing it to fall. If normal muscle tone is present the extremity will not strike the examiner's hand which protects the patient's face, but will fall to the side of it.

Examination of the abdomen is important in the conscious as well as in the unconscious patient. First, simple visual examination should be employed to determine whether the abdomen is scaphoid or distended and whether its movements are normal for a patient who is breathing normally with an uninvolved diaphragm. Next, the abdomen should be palpated for muscle guarding, tenderness and masses. The conscious patient can give considerable help by indicating whether or not there is tenderness in the abdomen and if so exactly where, as well as whether the tenderness is rebound in character. The palpation of the abdomen can be combined with gentle compression of the thoracic cage from side to side as a gross method of determining the possibility of rib fracture. If the abdomen is distended and the patient is unconscious, the abdominal examination should be extended to include careful auscultation of bowel sounds. If the patient is conscious and does not complain in particular of the abdomen, this phase of the examination may be postponed pending completion of the cursory examination of the lower extremities.

The pubic symphysis should be gently palpated and pressed against, just as the iliac crests should be subjected to gentle compression, in an effort to determine grossly whether or not there is a pelvic fracture. Both inguinal areas should be inspected and palpated for the possibility of a strangulated inguinal hernia. It is important to examine the perineum and buttocks in both male and female patients for any evidence of contusions and particularly for any evidence of

wounds which might involve the rectum at a higher level. The scrotum should be quickly palpated and the external urethral meatus of the male examined for gross evidence of bleeding. In female patients, the labia should be gently separated and the urethral orifice and introitus briefly inspected.

At this point, attention can be directed to the lower extremities as the final part of the emergency examination. The contour and symmetry of these extremities should be examined and then the tissue should be palpated gently but definitely in search for evidence of fracture of any of the long bones. In the conscious patient, voluntary effort should be requested to see that there is no limitation of motion of any of the major muscle groups or of any joints. In the unconscious patient, the thigh should be flexed passively on the abdomen with the heel still on the examining table and then released to determine whether the extremity will slide down in an externally rotated position indicative of paralysis.

Care of Simple Wounds. In the average hospital, simple wounds such as lacerations, contusions and even minor avulsions are treated in the emergency room. A simple rule of thumb for determining whether an injury is serious enough to require formal treatment in the operating room is that the latter is reserved for injuries in which deeper structures such as tendons, nerves, bones and blood vessels are involved. Obviously, head wounds of any severity, chest wounds, abdominal wounds, compound fractures and even simple lacerations of any great length or depth will require formal débridement and repair in a better-equipped operating room as opposed to the more simply outfitted emergency room.

All wounds should be gently cleansed with soap and water. This is best done by covering the actual wound with a simple, sterile gauze dressing while the skin about it is initially and briefly cleansed with soap and water, using frequent irrigations of soapy water or normal saline solutions from a separate container. When the skin adjacent to the wound has thus been cleansed, the wound itself should be similarly washed with soap and water and irrigated with saline solution. Irrigation is particularly important in wounds which have some depth or in which there has been considerable contusion of the soft tissue with indriven dirt and similar debris. It is usually accepted that a ten-minute cleansing with soap and

water coupled with saline irrigation provides the optimum preparation of the wound. At this point, the devitalized tissue should be excised and the various layers involved should be gently débrided, trimming away only the jagged and irregular edges and those pieces of skin, fat or muscle which are either obviously dead or so badly contused that their recovery is questionable.

Insofar as possible all foreign material should be removed. This is particularly true of clothing, hair and street dirt. However, considerable judgment must be exercised because sometimes a search for an innocuous foreign body, such as a small piece of metal which was hot at the time of its entry, may be more devastating to the tissue than simply leaving the foreign body in place. In some abrading injuries there is a great deal of tattooing of the skin in its more superficial layers. Endless time can be spent in attempting to pick out these small pieces of gravel or dirt, whereas most of them will slough if they are simply left alone and allowed to work out as the cells in which they are imbedded are pushed out toward the epidermis.

In wounds which have been adequately cleansed and débrided and which are seen within six to eight hours of their infliction, it is perfectly safe to close the skin edges primarily. In wounds which are seen after this "golden period" has passed, it is probably safest to leave the wound edges open. If upon inspection a week to ten days later the wound is clinically clean, it may be possible to close it secondarily as was done with many thousands of wounds in World War II and the Korean conflict. The closure need not involve actual suturing because sometimes sterile tape bridges or collodion-impregnated fine-mesh gauze bridges can be used to approximate these skin edges almost as effectively as actual suture material.

Care of Animal Bites. A wound produced by animal bite presents particular problems not usually present in wounds inflicted by inanimate objects. Dog bites are by far the commonest of animal bites and they always carry with them the risk of rabies. All such animal bites must be reported to the proper authorities, usually the local police station, but in some communities it is required that the bite be reported to the Public Health Department directly.

The wound is treated like any other wound and when adequately débrided and cleansed it may be closed primarily if it is seen sufficiently early. Special problems con-

cerning dog bites revolve about the question of whether or not the dog is rabid. If the dog can be positively identified and kept under observation, the patient need not be given any prophylaxis against rabies. If the dog was in a pre-rabid phase of the disease at the time the wound was inflicted, the animal can be expected to develop clinical signs of rabies within ten to fifteen days. At this time positive immunization of the patient with rabies vaccine can still be successfully undertaken. If the dog does not develop rabies during the period of observation, then the matter can be dropped.

Technically, human bites are in many ways much more serious than the average animal bite because the symbiotic action of Vincent's organisms found in the mouth of the human being produces an extremely virulent infection. For this reason, human bites must be given especially meticulous care and in most instances should not be closed primarily even if seen early.

Bites by other animals are quite infrequent but in many instances carry the same danger of rabies as do dog bites. Squirrels, skunks, cats, and other small animals have been known to transmit rabies to human beings. In the instance of a bite from such a small animal, if the animal can be kept under observation the same procedure is followed as is done with the dog. In most instances, however, it is impossible to make a positive identification of the animal, much less keep it under observation. Therefore, to be on the safe side, individuals bitten by such animals should be given the Pasteur antirabies treatment.

Protection against Tetanus. Many wounds carry with them the potential danger of tetanus. This is particularly true of wounds inflicted by rusty implements or nails and of wounds contaminated with street dirt or farm dirt. The spores of tetanus are known to be widely distributed in nature and to occur as contaminants of various animal furs and hairs. Since tetanus organisms are anaerobic, they will multiply best and elaborate their toxin in the depths of a closed wound. It is possible that they thrive even better in an infected wound where other pathogens are present to use the oxygen, thus producing a more truly anaerobic environment. Thus, one form of prophylaxis against tetanus consists of removing so far as possible contamination in the depths of the wound and in every way possible preventing any wound infection, however, this alone is not sufficient because tetanus car-

ries such a high mortality when it does occur. Therefore, two means of giving the wounded individual immunity are in use. The first is to confer passive immunity by means of tetanus antitoxin. The second is that of developing the patient's own active immunity to tetanus by means of tetanus toxoid.

An effective passive immunization which will last for at least one week can be conferred on an individual by giving *tetanus antitoxin* which is derived from the serum of horses. The standard dose has been 1500 units, but many physicians now are giving a minimum of 3000 units and some give 5000 units. This confers immunization immediately, but immunization is not effective longer than one week. If the wound for which this was given continues to be infected the dosage of tetanus antitoxin must be repeated. Because there is an appreciable incidence of sensitivity to horse serum, tetanus antitoxin should not be given to a patient without first testing the individual for sensitivity. This may be done by means of intradermal tests or, as some authorities feel, more effectively by means of conjunctival tests in which a drop or so of very weak solution of antitoxin is used. If there is a sensitivity and the situation requires definitely that antitoxin be given, it can be given in very small doses with some intravenous antihistamines and/or 5 mm of 1:1000 Adrenalin chloride. In some instances it may be necessary to use a rapid desensitization procedure.

Tetanus toxoid is an alum-precipitated toxin which has thus been rendered non-toxic but which retains its antigenic properties. It is given in a series of three doses, usually at biweekly intervals, to develop the individual's own immunity to tetanus. This procedure has many advantages over immunization with tetanus antitoxin, not the least of which is the fact that there is no real sensitivity to the tetanus toxoid. Occasionally a patient may develop a local reaction at the site of injection but this is transient and is never accompanied by systemic signs. Another advantage of tetanus toxoid is that the titer of immunity so produced can be raised to an effective level with a so-called booster dose of 0.5 cc of toxoid at long intervals after the original immunization series has been given. Authorities now feel that there is still a responsive level almost ten years after the original series of immunizations. It might be pointed out that tetanus toxoid cannot be invoked

as a means of protection against a particular wound. If the patient has not been previously immunized with tetanus toxoid, the level of antibody rises so slowly that it will not be effective in the particular instance where the possibility of tetanus is feared. Immunization with tetanus toxoid is definitely an interval procedure which is done in anticipation of the patient's receiving wounds in the future which might carry the risk of tetanus. Practically all youngsters today who are under the care of a family pediatrician are routinely immunized against tetanus. All persons entering the Armed Forces of the United States similarly receive immunization with tetanus toxoid so it is a relatively easy matter to determine whether or not an individual has had a previous immunization. If he has, then a booster dose of tetanus toxoid is all that is needed.

Care of Severe Injuries. When the house officer is confronted with a severe injury which requires care in the operating room, he must have a definite logical approach to the problem. This should have been thought out and planned in advance to the extent that it is almost second nature with him. The basic tenets of this approach are: keep the patient alive, find out what is the matter with him, get whatever help is needed; restore normal physiology as soon as possible. The tenets are listed in the order of their priority although they are obviously not mutually exclusive.

Although usually it is fairly obvious what must be done to keep the patient alive, occasionally, as in the instance of severe spontaneous pneumothorax or a recently perforating ulcer, the young surgeon may have to do a little searching to find exactly what is wrong with the patient before he can attempt to save his life. It may seem to some that the statement of four such tenets is unnecessarily fundamental. However, there are few surgeons who have not had the experience of seeing a befuddled intern, stunned by newspaper reporters and photographers, trying to placate the weeping relatives while attempting in his own mind to decide whether to summon an attending man, call the operating room, take the patient to the x-ray room or try to obtain a history. Such an intern, remembering these tenets, should immediately clear the emergency room of all relatives, bystanders, photographers and police while he makes a rapid assessment of the patient's vital signs and determines the degree of jeopardy. He should then institute symptomatic therapy

for what seems to him most threatening—oxygen for obvious respiratory distress; intravenous fluids for signs of shock—while having a sample of blood taken for immediate typing and crossmatching. He may then summon an appropriate attending man and send a nurse or emergency room aide out to ask the relatives or bystanders a few simple questions to fill in the clinical picture already developing from his findings, gleaned while he conducted the remainder of his emergency examination. Fulfillment of the final tenet usually involves definite treatment, surgically or medically, as the case may be—slow decompression of the affected lung in the spontaneous pneumothorax, closure of the hole in the duodenum in the instance of a perforating ulcer, alignment and immobilization of the fragments of a fractured bone or ligation of a severed artery in the instance of severe hemorrhage from a laceration. The intern or resident, however inexperienced he may be in handling emergencies, who knows what needs to be done and has a systematic way of achieving his objectives may be able to do as much for the severely injured or acutely ill patient as the most skilled and experienced physician. This matter of having a system for handling emergencies, a pattern for activity in the face of life-threatening wounds and illnesses, becomes even more important when the hospital is suddenly confronted with a mass influx of patients from some local catastrophe such as a fire, explosion, hurricane, flood or similar misfortune.

VENIPUNCTURE

Perhaps the most important feature of venipuncture is selecting an appropriate vein. Since the antecubital veins are usually quite prominent and fairly easily entered, they are often used for withdrawing blood samples. However, the amount of motion possible at the elbow makes them poorly suited for continuous intravenous infusion. Also, in a patient who is to require intravenous fluids over a period of many days, it is wiser to start as far peripherally as possible so that as thrombosis occurs there will still be veins available proximalward from the site of the first venoclysis. In general, the superficial veins on the flexor and extensor surfaces of the forearm are best for the administration of intravenous fluids. However, the veins of the foot are often easily used and the constancy and size of the greater saphenous vein at the medial malleolus make it a frequent site of election for venoc-

cerning dog bites revolve about the question of whether or not the dog is rabid. If the dog can be positively identified and kept under observation, the patient need not be given any prophylaxis against rabies. If the dog was in a pre-rabid phase of the disease at the time the wound was inflicted, the animal can be expected to develop clinical signs of rabies within ten to fifteen days. At this time positive immunization of the patient with rabies vaccine can still be successfully undertaken. If the dog does not develop rabies during the period of observation, then the matter can be dropped.

Technically, human bites are in many ways much more serious than the average animal bite because the symbiotic action of Vincent's organisms found in the mouth of the human being produces an extremely virulent infection. For this reason, human bites must be given especially meticulous care and in most instances should not be closed primarily even if seen early.

Bites by other animals are quite infrequent but in many instances carry the same danger of rabies as do dog bites. Squirrels, skunks, cats, and other small animals have been known to transmit rabies to human beings. In the instance of a bite from such a small animal, if the animal can be kept under observation the same procedure is followed as is done with the dog. In most instances, however, it is impossible to make a positive identification of the animal, much less keep it under observation. Therefore, to be on the safe side, individuals bitten by such animals should be given the Pasteur antirabies treatment.

Protection against Tetanus. Many wounds carry with them the potential danger of tetanus. This is particularly true of wounds inflicted by rusty implements or nails and of wounds contaminated with street dirt or farm dirt. The spores of tetanus are known to be widely distributed in nature and to occur as contaminants of various animal furs and hairs. Since tetanus organisms are anaerobic, they will multiply best and elaborate their toxin in the depths of a closed wound. It is possible that they thrive even better in an infected wound where other pathogens are present to use the oxygen, thus producing a more truly anaerobic environment. Thus, one form of prophylaxis against tetanus consists of removing so far as possible contamination in the depths of the wound and in every way possible preventing any wound infection; however, this alone is not sufficient because tetanus car-

ries such a high mortality when it does occur. Therefore, two means of giving the wounded individual immunity are in use. The first is to confer passive immunity by means of tetanus antitoxin. The second is that of developing the patient's own active immunity to tetanus by means of tetanus toxoid.

An effective passive immunization which will last for at least one week can be conferred on an individual by giving *tetanus antitoxin* which is derived from the serum of horses. The standard dose has been 1500 units, but many physicians now are giving a minimum of 3000 units and some give 5000 units. This confers immunization immediately, but immunization is not effective longer than one week. If the wound for which this was given continues to be infected the dosage of tetanus antitoxin must be repeated. Because there is an appreciable incidence of sensitivity to horse serum, tetanus antitoxin should not be given to a patient without first testing the individual for sensitivity. This may be done by means of intradermal tests or, as some authorities feel, more effectively by means of conjunctival tests in which a drop or so of very weak solution of antitoxin is used. If there is a sensitivity and the situation requires definitely that antitoxin be given, it can be given in very small doses with some intravenous antihistamines and/or 5 mm of 1:1000 Adrenalin chloride. In some instances it may be necessary to use a rapid desensitization procedure.

Tetanus toxoid is an alum-precipitated toxin which has thus been rendered non-toxic but which retains its antigenic properties. It is given in a series of three doses, usually at biweekly intervals, to develop the individual's own immunity to tetanus. This procedure has many advantages over immunization with tetanus antitoxin, not the least of which is the fact that there is no real sensitivity to the tetanus toxoid. Occasionally a patient may develop a local reaction at the site of injection but this is transient and is never accompanied by systemic signs. Another advantage of tetanus toxoid is that the titer of immunity so produced can be raised to an effective level with a so-called booster dose of 0.5 cc of toxoid at long intervals after the original immunization series has been given. Authorities now feel that there is still a responsive level almost ten years after the original series of immunizations. It might be pointed out that tetanus toxoid cannot be invoked

ber beneath the intravenous fluid bottle will tell whether the flow of blood is being compromised by any of the fixation procedures.

As a final step, it may be necessary or desirable to place the extremity used for the intravenous administration on an arm-board or other splint. This is mandatory, of course, when the vein being used is one on the back of the hand or on the foot. When the vein is on a relatively flat surface on the extensor part of the forearm or on the flexor surface, the forearm itself may provide sufficient immobilization of the vein.

"Cut-down" and Cannulating of a Vein. Occasionally it is desirable to have a more dependable route for administration of intravenous fluids or blood than is afforded by the ordinary venoclysis procedure. In such instances a vein, usually the greater saphenous at the medial malleolus, is exposed by cutting down on it after the surrounding area has been locally anesthetized. The distal end of the segment exposed is then tied and the ligature held with a hemostat to provide traction on the proximal portion of the vein. Another ligature is passed under the proximal end of the exposed segment and one tie taken loosely. The middle of the exposed segment is then partly cut through with a small scissors of the manicure type. The V-shaped flap of vein wall thus produced is gently lifted up by a small tissue forceps while a cannula is slipped into the lumen immediately beneath it far enough for the knob on the cannula to lie proximal to the loose tie (Fig 2). The tie is then secured by squaring the knot and taking an additional loop in that knot. This ligature is cut so as to leave the ends $\frac{1}{4}$ to $\frac{1}{2}$ inch long.

Figure 2. Method of "cut-down" and cannulating of vein for introduction of fluids.

This facilitates the subsequent cutting of the knot and removal of the cannula when the intravenous therapy is to be discontinued. The distal knot is cut flush as it will be left in. One or two skin sutures are placed in the skin and taken down loosely, so that the cannula may be subsequently removed and the ends of the ligatures then drawn down snugly and tied to close the skin wound. It is important to note the location of the greater saphenous vein before making the cut-down so that the incision can be made in the proper place. The cut-down should be made parallel to the direction of the vein instead of transversely so as to facilitate the exposure of a fairly long segment of vein through a relatively small skin incision paralleling it. A transverse wound must be unduly long to permit the exposure of an adequate segment of vein. After the cannula has been well placed, fluid should be started immediately to keep the blood from clotting in the cannula.

An alternative to the use of the cannula is the placing of an indwelling polyethylene tube. This method of giving intravenous fluids is particularly popular when the fluids must be given for many days, or even weeks. The cut-down is accomplished in the same way as it would be for cannulation. Usually it is not necessary to place a tie distal to the opening in the vein because the pressure of the tubing below the cut-down against the distal segment of the vein occludes it. If the size of the tubing is such that it fits snugly in the vein and if it is fed proximalward for at least 3 inches, there should be no retrograde leaking of blood or fluid through the wound. A snug pressure dressing over the cut-down wound helps to prevent such leakage.

CARE OF MECHANICAL EQUIPMENT

Surgical techniques have now advanced to the point where one is often dependent to great degrees upon mechanical aids, such as suction and tidal drainage systems, sump arrangements and underwater drainage bottles like those used in draining the pleural space after thoracotomy. These mechanical aids are accepted and employed so routinely that often it is not realized how significantly they may affect the success or failure of a given operative procedure. A simple account of selected incidents cannot begin to give a connotation of the misery for the patient and the heartache for the surgeon who are both victims of mechanical failure, but it may serve to alert the members of the surgical

lysis, particularly when this is accomplished by cut-down and the placing of a cannula.

Obviously the vein must be full to be located and particularly to be entered by the needle. Superficial veins are best filled by occluding their centripetal flow by means of a blood pressure cuff placed above the vein and inflated to a pressure of 40 mm. of mercury. Usually it is not necessary to invoke such an elaborate procedure and an ordinary tourniquet can be gently tightened around the arm or leg above the place where the venipuncture is to be done. Active or passive contraction of a muscle distal to this tourniquet will free more blood to fill the chosen vein.

Different individuals have different ways of making the actual introduction of the needle into the lumen of the vein. The beginner will do well to bear several fundamental facts in mind. First, the segment of vein which is to be entered must be relatively fixed so as to offer some resistance to the point of the needle. This fixation is best accomplished by drawing back on the skin over the vein at a distance of 1 to 2 inches below the projected site of puncture, this leaves a segment still filled with blood relatively fixed so that it does not roll over the point of the needle (Fig 1). Second, when it is felt that the point of the needle lies against the wall of the vein a short, swift jab is required to put the point of the needle, which is impinged against the wall, actually through the wall. A little experience will teach the beginner much about the amount of force that is required for this maneuver. However, the stroke should be short so that the needle does not go completely through both walls of the vein and it should be directed at an acute angle to the vein wall, preferably with the open end of the needle facing out away from the vein wall instead of down and parallel to it. Once the tip of the needle is in the vein a meticulous effort should be made to feed the needle slowly into the lumen of the vein so that at least an inch of it is inside the lumen. With the needle held at its point of entrance through the vein wall, this gives a long arm and consequently poor mechanical advantage to any movements which might force the tip of the needle through the vein at still another point, consequently it makes it much less likely that the needle will come out of the vein or that there will be any extravasation.

The moment of entry of the needle through the vein wall is usually signalled by the appearance of a small spurt of blood just

Figure 1 Fixation and puncture of superficial vein for introduction of intravenous fluids.

proximal to the hub of the needle within the syringe or the intravenous tubing. If one feels that the needle is in the vein and yet the spurt of blood fails to appear, gentle traction may be made on the column of blood by pulling back on the plunger of the syringe or by milking back on the tubing to invoke such an outpouring. If blood still fails to appear and one is still certain that the needle is within the lumen of the vein, the injection should be given slowly or the clamp on the intravenous fluids released to allow flow of a small amount of fluid. If the needle is out of the vein, there will be immediately a swelling at the site where the fluid is being deposited outside the vein wall. In this event, the venipuncture must be attempted again at a point proximal to the point of failure. The latter point, the site of the original entry, should be covered with a small dressing and pressure maintained to prevent undue extravasation of blood through the point of rupture of the vein wall.

Once the needle is well established in the lumen of the vein, it must be fixed to the skin to prevent its being dislodged subsequently. This is best done by placing a small gauze pad under the hub of the needle and then placing adhesive tape over the hub and gauze to hold the needle down against the skin. Additional pieces of tape should be used to hold the intravenous tubing to the skin at a point 3 to 4 inches beyond the site where the needle entered the vein. In all this taping and positioning of the needle, one must be sure that the tip of the needle is not angulated against the wall of the vein or that the pressure is not so severe as to cause the needle to push the vein wall down into the tissues beneath it and thus occlude the flow of blood past the needle. Observation of the dripping of the fluid within the glass cham-

ods of performing any given procedure to accomplish the same result.

Surgical Dressings. The application of surgical dressings is an old and time-honored procedure which is done differently by various surgeons. The basic principle in applying a surgical dressing is that it should be done with the same precision and careful attention to aseptic technique as is practiced in an operating room. Such an exacting end can be achieved by the simplest management of details by the attending surgical staff with the help of a cooperative and intelligent house staff.

In most modern hospitals, satisfactory provisions have been made for surgical dressings by means of dressing trays or carts. In some institutions, individual packages are wrapped with materials for individual dressings. Regardless of the technique of carrying the dressing equipment and materials to the patient's bedside, the basic principle should be the same.

The equipment on the standard surgical dressing cart should include sterile canisters which contain gauze dressings of various size, depending on the particular type of work being done on the service, standard sizes being 3-inch and 4-inch square gauzes. There should also be canisters containing sterile towels. Other canisters will be filled with smaller gauze squares, sterile test tubes and applicators for the ready culturing of drainage from wounds. A variety of hemostats, forceps and scissors should be assembled in a flat, sterile, covered basin and there should be bottles for the various types of solutions which are used in changing dressings. Also included should be various types of thicker pads containing either cotton or cellulose material, sterile and wrapped in toweling. These dressings will vary in size, depending upon the nature of the surgical service. Most surgical dressing carts should contain pads, 8 by 12 inches in size, which are commonly labeled "ABD pads," signifying abdominal dressings, but which, of course, may be used for other purposes as well. At some institutions larger pads of the same type are labeled "arm pads," since they will enclose an entire extremity. When a great many burned patients are being taken care of, even larger dressings of this same general type should be available. Various sizes of gauze, roller bandage, elastic bandage, muslin bandage and adhesive tape should also be supplied on the dressing cart.

Provision should be made for the collection of soiled dressings which should not be

allowed to touch the bedclothes or the sterile canisters on the cart. In some institutions, provision is made for these dressings by means of a garbage-can type of container on the floor in the hospital or attached to the dressing cart so it may easily be removed. This should be covered so as to prevent insects from spreading the organisms about the hospital. Provision is also made for the collection of used or soiled instruments on the cart which may be returned to the central supply depot for re-sterilization and re-use.

The solutions on a surgical dressing cart vary somewhat with the desires of the particular surgeon involved. On most dressing carts, such solutions as benzine, acetone and alcohol which are necessary in removing adhesive tape from the skin are commonly present. Most modern dressing carts do not have the stronger antiseptic agents on them since few surgeons employ these agents which were so commonly used in the past, but they do contain a bottle of liquid soap, or one of the emulsifying agents, for use in cleansing skin. Also available should be flasks of normal saline solution and of sterile water. There should be a lifting forceps immersed in alcohol in a jar of some type, either metal or glass. This sterile forceps is used for lifting materials from the sterile canisters for each dressing so that the canisters will not be contaminated by repeated use of the same instruments which are employed in doing the dressings. Surgical masks should be required supplies; sterile gloves and gowns may be provided as desired.

Regardless of the type of special dressing which may be needed in a particular case, the technique of handling all dressings should be essentially the same. All in attendance, including the patient, should have on a surgical mask to prevent the contamination of the wound by organisms from the mouth and nose. At the patient's bedside, a sterile towel is removed from the canister by means of the lifting forceps and spread out on a convenient bedside or overbed table. It has been found useful to place a piece of folded newspaper beneath this towel to protect the surface of the table from any of the solutions which may reach it. Toward the edge of this towel are placed one or two sterile hemostats and forceps from the tray containing the instruments, and scissors if these are needed. These instruments are placed with the handles close to the edge so that they may be picked up without contaminating the center of the sterile towel.

house staff to the importance of simple attention to all mechanical aids.

A patient who had had a subtotal gastrectomy was returned to his room in good condition with the Gomco suction working

F
o
t

well. Unfortunately, no member of the house staff was available to examine it or to make sure that it was properly irrigated and that its function was re-established. When the patient was finally seen after 3 P.M., a few blood clots were aspirated through the small-caliber Levin tube, but the patient's general condition made it obvious that he was bleeding into the stomach and that large clots had formed, making it necessary for him to be returned to the operating room. There the gastrojejunostomy was taken down and the stomach emptied of approximately 1200 cc. of blood, most of which was clotted. No discrete bleeding point was found in the site of the anastomosis and the general conclusion was that had the suction been working well the stomach would not have become sufficiently distended to allow continued oozing from the stoma.

A patient on whom a mitral valvulotomy had been done withstood the procedure quite well. Her chest was closed with two drainage tubes leading out from the pleural cavity to 1000-cc flasks filled with 700 cc of sterile water. The drainage tube was connected to a piece of glass tubing which emptied well beneath the surface of the water in the bottle. In one of the bottles the glass tube had been cracked at a level above that of the water. When the patient was being put into bed and the jars adjusted on the floor, the broken piece of glass fell off its insecure connection to the tubing which returned through the cork of the bottle. This permitted immediate influx of air into the patient's pleural cavity and a pneumothorax of several thousand cubic centimeters developed almost at once in this patient whose condition was serious at best. The source of the difficulty was immediately detected and the drainage tube was clamped until oxygen under pressure could be administered through an endotracheal tube and the lung blown out at once, as the air which had been inadvertently allowed to enter was exhausted through the other underwater seal.

An elderly woman who had been subjected to choledochotomy for numerous common duct stones, which had produced jaundice, was returned to her room in fairly

good condition but had a period during which she was somewhat irrational. At this time she managed, in thrashing around, to pull out the T-tube which had been inadequately secured to the skin of the abdomen. Another operative procedure was required to replace the T-tube and, of course, this second operation was an unnecessary demand on her feeble reserves. Fortunately she survived, but on the seventh postoperative day developed a biliary fistula about the T-tube which required sump drainage with a Chaffin tube and Stedman pump. Because of an unnoticed kink in the tube connecting the Chaffin sump tube to the pump, no effective pressure was put on the sump arrangement for twenty-four hours. When it was noticed that there had been no drainage accumulating, more careful attention was paid to all details of the apparatus and the obstruction was immediately detected. When this was relieved there was a gratifying return through this sump.

Every surgeon could elaborate at some length on this brief list of misadventures resulting from failure of mechanical equipment—failure contributed to by the negligence of nurses or doctors, failure which should have been noticed in time to prevent the difficulties enumerated. For example, most surgeons have had T-tubes and catheters whose lumina were plugged with debris, the presence of which they have detected by testing the equipment before using it.

Nothing can be taken for granted in the utilization of mechanical aids in the care of surgical patients. Every piece of equipment must be checked before it is used and its continuing function must be checked at frequent intervals as long as the patient is dependent upon that particular equipment.

SURGICAL TECHNIQUES

The senior surgical clerk often approaches his clerkship in a hospital with little or no knowledge of many of the technical procedures which he is asked to perform. First-year surgical interns who have not had a broad general surgical clerkship may also have had no contact with many of the procedures which are commonly performed in a hospital by a junior surgical intern. The techniques of these various procedures are obviously best taught person to person by one of the surgical residents, or attending staff of the hospital, directly to the man involved. Of course, there are several meth-

a better inflow of arterial blood with more effective, rapid healing. Compression dressings are often used in the treatment of burns on the head, the chest and the extremities. Such dressings are difficult or impossible to apply on the abdomen and seldom find a useful place there except possibly in the instance of burns. The general principle in applying a compression dressing is that the compression must be uniform and not tight in any particular locality so as not to obliterate venous return or arterial inflow into a part. The gauze dressings are applied in a manner basically similar to that used for general dressings. The gauze protective dressing is then padded with a mass of either fluffed-up dressings derived from "flats" of gauze or, as in some institutions, sterile mechanic's waste. Another material often used for compression is sponge—either synthetic rubber or sea sponges. These materials are then bound down by an elastic bandage which may be reinforced or tightened by means of safety pins or adhesive tape. The materials for an elastic bandage vary somewhat with different institutions.

On the chest the most commonly used materials for compression dressings, particularly after radical mastectomies and procedures of that type, are stockinet of sufficient width, usually 6 inches, or elastic bandages which may be the two-way stretch type or rubberized elastic bandages. The elastic type bandage used on the extremities may be of either of these types as well. An important fact to remember is that such a dressing applied to an extremity must start at the distal end of the extremity and extend proximally as far as desired and not in the reverse direction. Leaving an exposed area of extremity below such an elastic compression dressing usually results in edema and discomfort and may actually do harm to the patient. Elastic type compression bandages have a wide usefulness but are particularly helpful in the handling of burns and open wounds. They also have considerable utility in the dressing of any wound about an extremity, but one must avoid extreme pressure over the bony prominences, which must be well padded. The dressing must be applied smoothly and without wrinkles, which are uncomfortable to the patient and may produce undue pressure in a particular spot. It is usually applied without reversing the bandage as is done in placing a roller bandage.

For large wounds of the scalp and for craniotomy incisions, the most satisfactory dressing is one designed by Cushing which

employs a 5-yard roll of sterilized gauze 5 inches in width. After applying the original dressing, two turns of the 5-yard roll fix the dressing about the forehead and occiput. The roll is then taken down under the chin and while an assistant holds this gauze under the chin at a convenient distance so as to prevent making it too tight, two or three turns are made over the vertex so as to cover the remainder of the head completely, going under the chin each time. It is then turned back to complete the circle around the forehead and occiput to fix this chin strap. The turns of this dressing are then fastened in place by means of safety pins which may be twisted so as to tighten the whole into a snug, close-fitting dressing. Straps of 1-inch adhesive or ties of 1-inch roller bandage are then applied about the chin strap, one on each side in front of the ear and one at the bottom of the loop under the chin so as to make a single, neat, compact chin strap. Several pins are then applied between the circular layers about the forehead and occiput and the deeper layers over the head so as to fix the latter firmly in place. This dressing is so secure, if properly applied, that even a disturbed patient who is not responsible for his actions may have difficulty in getting it off (Fig. 3).

For small lacerations or incisions in the scalp, sterile fine-mesh gauze made adherent to the skin by means of flexible collodion makes an excellent dressing. The gauze is trimmed to appropriate size from a sterilized roll of gauze roller bandage; usually four to six layers of this material are incorporated in the dressing. After being trimmed with the sterile scissors to the size desired, a layer at a time is applied to the scalp over the wound and the flexible collodion is painted

Figure 3 Diagram of Cushing type head dressing

Various quantities of dressings of appropriate sizes are placed on the towel. Then everything is in readiness for the changing of the dressing.

It should be stressed that unless it is absolutely necessary for adhesive tape to be removed from the patient's skin each time a dressing is changed, it is better to clip the tape with a pair of bandage scissors at the edge of the dressing so as to avoid the irritation caused by the repeated application and removal. The outer part of the old dressing is discarded onto a newspaper which can be folded up and placed in the receptacle provided for dirty dressings. The deeper dressings next to the wound are removed by means of the sterile instruments that were placed on the sterile towel. These dressings are likewise dropped on a paper for discard. Frequently, the first dressing may be somewhat stiff and adherent to parts of the wound because of the collection of serum or even blood which has dried on the dressing. As a consequence, the dressing should be removed cautiously to prevent pain to the patient as well as injury to a healing wound. Experience in doing this thoughtfully and carefully with concern for the patient's comfort increases the dexterity and skill of the operator.

Once the dressing has been removed the wound may be inspected but should not be touched with the fingers since it is regarded as relatively sterile. If sutures are to be cut or removed, this is done carefully using sterile instruments from the sterile towel and avoiding contamination of the working portions of these instruments. If the sutures are removed, it is often found helpful to apply support to the skin which, though healed, may be easily separated by ordinary pull which may produce an unnecessarily wide scar. Materials most commonly used for support to the skin are adhesive bridges made by folding under the portion of the adhesive tape which will come in direct contact with the wound. These bridges are made relatively clean by cutting them with clean scissors and then painting them with an antiseptic solution or flaming them. They are applied in such a manner as to take the tension from the healing wound. They are particularly useful in a long wound and it is better that they be applied as the sutures are removed, rather than afterward, since the sudden movement of the patient may separate the wound. Another excellent material for relieving tension from the healing wound is fine-mesh gauze, usually obtained

from roller bandage, which has been sterilized and is cut into short strips and made adherent to the skin by means of flexible collodion applied with sterile applicators to the whole of each strip of gauze.

Sufficient gauze dressings are reapplied to the wound by means of sterile hemostats or thumb forceps to cover the wound adequately. This means an overlap at both ends of the wound of perhaps 1 or 1½ inches and 2 to 3 inches on each side. This dressing is usually covered by an abdominal pad or some thicker layer of material which prevents further contamination.

The smallest amount of fixation possible in abdominal wounds is advisable. The amount of irritation to the skin from adhesive tape, which is most commonly used to fix these dressings in place, is reduced by using a minimum of tape. However, tape strips should be long enough to fix the dressings well so that they do not slip off. The use of any sort of liquid on a healing wound that is dry and clean seems superfluous. A wound that is open or draining, of course, should be cleansed and the most satisfactory materials for this are soap and water, which should be sterile, applied with sterile gauze sponges held in the hemostats and thumb forceps supplied on the dressing carts.

Unused gauze which has not been soiled, but has been brought out of the sterile containers, is never returned to the containers but is placed in a receptacle provided for that purpose, to be returned to the central supply room for re-sterilization.

Although the technique for surgical dressings described above may seem time consuming to those who have been somewhat less formal about dressings, it is a safe and a sure one for preventing contamination, regardless of the type of wound involved, and is a sound one for young surgeons to develop.

Within the last few years, hospitals in this country and abroad have been plagued by severe and often fatal surgical infections in which the offending organism was a coagulase-positive staphylococcus. In the face of this extremely grave problem, the importance of following a good aseptic surgical dressing technique cannot be overemphasized.

Special types of dressings. Most surgeons have found that mild elastic compression upon wounds is helpful in the healing process. This is true because support of the venous system, particularly in the extremities, improves drainage from the area so that less edema occurs and consequently there is

the wound thoroughly with a safe margin on each side. Such dressings are usually fixed by means of adhesive tape, the narrowest type practicable for the size of dressing being used. If some support for the abdominal wall is desired with the dressing, it is common practice to use 2-inch tape. In those cases in which this is not necessary, 1-inch adhesive tape straps supply enough protection with half as much irritation to the skin. For repeated dressings upon abdominal wounds of smaller size, even $\frac{1}{4}$ -inch adhesive straps may be used. It should be emphasized that although these straps must go far enough past the edge of the gauze to become firmly adherent to the skin they need not cover large expanses of skin which would lead to unnecessary irritation. If on changing dressings such adhesive straps are cut at the margin between the adherence to the skin and the adherence to the gauze, rather than being removed each time, much less irritation of the skin occurs. The new straps can be applied over the old and, in the average elective case, by the time it is unnecessary to have further dressings the elastic adhesive will be so free as to be readily removed without much pain to the patient. Another means of preventing irritation to the skin from adhesive tape is to treat the skin with tincture of benzoin before the application of the tape.

Spinal Puncture. Lumbar puncture is a procedure which is often done on surgical and medical patients. Every house officer should try to develop facility and dexterity in this useful procedure. Depending upon the circumstances for which the puncture is done, the patient may be put in a sitting posture or may be laid on his side. In either position it is important to have flexion of the lumbar spine so that the spinous processes adjacent to the fourth interspace, the usual site of puncture, be opened as much as possible. When the puncture is done with the patient lying on his side, this can be effected by having him bring his knees up on his chest and bend his head down upon his chest. With the patient in this position it is important that he be brought well to the edge of the bed where the added support of the bed frame will maintain the relatively straight alignment of the vertebral bodies, as opposed to the scoliosis which may occur on a soft bed when a patient is allowed to lie on the center of it.

The house officer should never attempt a lumbar puncture without previous instructions from his attending surgeon and should

always be supervised in his initial attempt at this procedure. Sterile technique should be observed in that those present should wear caps and masks and those actually doing the procedure should wear sterile gloves. The skin should be scrubbed over a wide area from the sacrum up to the lower thoracic spinous processes and from one flank to the other, using soap and water. It should be draped with sterile towels. The point directly between the tips of the third and fourth lumbar spinous processes in the midline should be injected with 1 per cent procaine until a 1-cm. wheal has been raised. Then, with a longer needle inclined slightly cephalad but maintained directly in the midline, the injection should be continued as the needle is pushed forward to infiltrate the interspinous ligament. Usually infiltration need not be carried deeper than 2 inches. The spinal puncture needle is introduced into the skin with a short thrust and then slowly pushed inward. If it is arrested by striking bone, the needle should be pulled out and introduced at a less acute or more acute angle as the case may require. Although its inclination somewhat caudad of perpendicular may be altered to some degree, the needle must be maintained exactly in the sagittal plane at all times.

When the needle has finally penetrated the spinal canal, this event will be signalled by its suddenly "falling into" this space. It is imperative that the needle be guided by both hands and that it be always held in such a manner that it cannot penetrate too deeply in a sudden thrust when the resistance of ligaments ahead of it gives way. This, of course, is the principle in all procedures involving the introduction of a needle into a hollow cavity. When the needle is in the spinal canal, the stylet is gently withdrawn to see whether spinal fluid will drip from it. If the needle is correctly placed, there will be a slow dripping of fluid from the hub of the needle. If there is no such dripping, the needle may be presumed not to lie in the spinal canal and it should be withdrawn and reinserted gently and slowly. If the needle is advanced too far, it will strike nerve roots and the patient will complain of sharp pain, usually down the back of the thigh. If on withdrawing the stylet the operator obtains a flow of blood, the needle should be withdrawn and the puncture attempted at a different level. Once an adequate flow of spinal fluid is obtained, the stylet should be inserted in the needle while preparations are made to attach a three-way stopcock for de-

on with an applicator around the periphery of the gauze, layers being added one after another with collodion being applied to the edges of each layer to make it adherent. This produces a neat dressing which does not become involved with hair and will remain in place for several days. These dressings are useful for wounds on the face or an exposed extremity where not too much is needed to cover the wound. An occasional patient is sensitive to collodion and may develop skin irritation from its use.

Compression dressings on the chest are usually applied following radical surgery upon the breast. These are used primarily because the large skin flaps necessary in this operation have to be kept firmly in place against the deeper structures in the chest wall if they are to adhere without the accumulation of fluid beneath them. A similar type of dressing is sometimes used by thoracic surgeons after extensive procedures on the chest. However, the need for skin flaps in this situation is unusual and therefore compression is not so essential as it is following radical mastectomy or skin grafting to the chest wall. After the usual occlusive dressing is applied over the wound, a large mass of resilient material such as fluffed-up gauze or mechanic's waste is mounted up in bulky and generous fashion over the area for which compression is wished. It is important to make certain that any bony prominences which may be encountered in applying the dressing are covered well with padding. The dressing is usually started with a 6-inch stockinet roller at the waistline and is fixed there by two turns of stockinet around the waist pinned in place with safety pins. This is continued as a simple roller bandage overlapping some 50 per cent on each turn until the entire chest is covered, running from the back up over the shoulder on the involved side, catching the arm in a figure-of-eight spica, and coming back after encircling the arm to go once more around the chest, thus completing the spica bandage. This type of compression can then be tightened by means of safety pins, as in head dressings, so that firm compression can be maintained with comfort to the patient and without embarrassment of the respiratory function. Such a dressing is often left in place for three, four or five days, depending

firmer pressure and more effective dressings result with the use of the stockinet.

Recently some surgeons have dispensed with the use of heavy compression dressings. To prevent the accumulation of serum and blood beneath widely undermined skin flaps, they have resorted to a type of sump drainage. This involves the placing of catheters or polythene tubes beneath the skin flaps where fluids might be expected to accumulate. These tubes have several holes of generous size cut into the part which is to be buried. The outer end of the tube is connected to a Gomco suction apparatus. If this technique is properly employed, it prevents the accumulation of fluids beneath the skin flaps and eliminates the need of bulky dressings.

Often it is better not to use dressings about the face if the patient is to be kept in a sheltered location such as a hospital room, since the application of any dressings to small wounds may result in collection of serum or a few drops of blood along the suture line. The blood or serum may harden and interfere with the healing process, particularly if the dressings are removed without the greatest of care. This is especially true of the face because dressings often are taken off quite early to permit removal of the suture material in the skin in order to prevent scarring due to the sutures themselves. Wounds of the face treated without dressings are simply wiped off intermittently every few minutes for the first hour or two by means of a sterile applicator gently rolled over the wound so as to pick up any small amount of serum or blood which may have accumulated on the wound. After one or two hours these wounds, if they have been properly closed, are quite dry and sealed so that further contamination by bacteria is unlikely, especially if the hands and foreign materials are kept away from them. For nicely closed fresh wounds, this is a satisfactory procedure. For patients who are to leave the hospital or doctor's office, some sort of a dressing should always be applied. The most satisfactory dressing on the face for small wounds is a fine-mesh gauze collodion dressing. For those wounds about the face which need compression dressings, one must be improvised from some of the materials which have been mentioned, depending upon the location of the injury or wound.

Dressings on the abdomen need not be too large, or too thick, since in the average clean, elective case they are not expected to absorb purulent materials. They are simply used to prevent contamination of the wound by bacteria from the air, bedclothes and fingers. However, abdominal dressings should cover

sion, but often for diagnostic aspiration of minor effusions which are thought to have resulted from neoplasms of the lung. Unless circumstances dictate otherwise, puncture is usually made in the posterior axillary line at the lowest level in which it is expected that fluid can be encountered. This level is determined by percussion and x-ray findings. The puncture of the pleural cavity is usually made with the patient in the sitting position, although circumstances may require that the patient be left on his side. Many surgeons feel that the patient should be given $\frac{1}{150}$ grain of atropine at least one-half-hour before the procedure to eliminate any possibility of a noxious reflex mediated by the vagus nerves. The procedure should be done under conditions of sterile technique with the house officer capped, masked and wearing sterile gloves. The skin may be scrubbed widely with soap and water, or iodine and alcohol, or another acceptable antiseptic used.

The field is draped with sterile towels. A 1 per cent solution of procaine is injected into the skin to produce a wheal through which the deeper tissues are infiltrated with another 5 to 10 cc. of the same anesthetic. The thoracentesis needle is slowly introduced through this infiltrated area just beneath the edge of the rib until the feeling of resistance suddenly disappears and the needle sinks in rather quickly. The house officer should be prepared for such an event and should be holding the needle so that it cannot suddenly fall into the pleural space to any depth. The pleural fluid is usually withdrawn by means of a three-way stopcock which prevents the influx of air into the pleural cavity. When the thoracentesis has been performed for relief of pneumothorax, it is particularly important that this precaution be observed. It is also important that a large pneumothorax not be aspirated too quickly, as a sudden shift in the mediastinal contents could produce cardiac distress.

When the aspiration has been completed, the needle is quickly withdrawn through sterile gauze held close about its point of entrance through the skin. The area is then sealed with a small piece of cotton impregnated with collodion.

OBSERVING THE AMENITIES

Any member of the house staff who enters a patient's room, or comes to the bedside of

Dr. Jones' associate" or "I am Dr. O'Brien, a resident on Dr. Jones' service." There can never be any excuse for omission of this simple act of courtesy when an individual member of the house staff comes into contact with a patient. The attending surgeon will usually make such introductions on the first visit he makes to the patient in company with his intern and/or resident, but he knows that these men usually have seen the patient in the hospital before he has, so that introductions are not necessary.

Before the intern or resident undertakes any procedure with the patient, even so simple a thing as taking his history, he should tell the patient simply but in a clear manner just exactly what he plans to do. This may seem very fundamental, but far too many patients are examined, questioned, subjected to rectal examination, venipuncture and sometimes even spinal puncture without any preliminary explanation of what is about to take place. This is discourteous and leads to misunderstanding, fear and resentment. It is particularly important in dealing with children that simple, yet adequate, explanations be given in advance of any surgical procedures, even though it be so minor as the drawing of blood or the changing of a dressing. Children tolerate pain and unpleasantness surprisingly well if they have been warned about it in advance and if they do not feel they have been deceived by those who are caring for them.

Of course, the young surgeon's concern for propriety in relationships with the patient is not limited to the patient's room. When the patient is being taken to the operating room, it is imperative that the trip be made as smooth as possible. The cart should be handled gently and not bumped in the course of moving the patient from his room to another floor for surgical procedures. In the course of such a trip conversation between the house officer and the patient, if there is to be any, should relate to innocuous subjects. If there is any discussion of the forthcoming procedure, it should be brief and reassuring. The attending surgeon will, of course, have prepared the patient in advance for what is to occur in the operating room and, therefore, the house officer should do nothing to disturb the patient's serenity, presumably already achieved by preoperative medication.

In the operating room and in the corridors of the operating suite, it is essential that an air of quiet prevail. Laughing, loud talking and even persistent whispering are incom-

For example, I am Dr. Smith,

termination of manometric pressure and collection of fluid samples. If the puncture has been made while the patient is in the sitting position, it is extremely important that a minimum amount of fluid be allowed to escape, since a sudden lowering of pressure could cause a herniation of the cerebellar tonsils through the foramen magnum. When increased intracranial pressure is suspected, the puncture should not be done with the patient sitting.

After a three-way stopcock has been attached, manometric pressures can be determined and spinal fluid samples collected. The stylet is then replaced in the needle and a small sponge is placed on the skin around the needle while the needle is quickly withdrawn. The puncture site is covered with a small piece of sterile cotton impregnated with collodion, this makes an adequate seal for the wound.

At the conclusion of the procedure, the patient should be instructed not to raise his head or to move about vigorously in bed as such activity may induce the so-called post-spinal puncture headaches. Twenty-four hours after the lumbar puncture, it is safe for the patient to do whatever was permitted before the procedure.

Passing the Stomach Tube. Occasionally in the emergency room, it will be necessary to empty a patient's stomach. In such instances a large Ewald tube is usually employed and it is passed through the mouth. It may be necessary to pass it on an unconscious patient, e.g., one who has taken an overdose of sleeping pills in a suicide attempt. The tube should be cold and lubricated with ice water or mineral oil, it should be arched posteriorly as much as possible so as to avoid an endotracheal passage. Once the tube is in the esophagus, it should be passed quickly until it is in the stomach. At this point a large aspirating bulb is applied to the end of the tube and the contents of the stomach quickly aspirated. Should the tube be inadvertently passed into the trachea, usually a tremendous gag response will be evoked. Should there be any question at all whether or not the tube is in the trachea, the issue can easily be settled by feeling the outer end of the tube for evidence of expiratory movement of air out of the tube.

In most instances the stomach tube used is a much smaller one, usually a Levin tube, which is passed through the nose and then through the pharynx and down the esophagus into the stomach. In many instances it is done as a preliminary step to some type

of surgery on the gastrointestinal tract in an effort to eliminate postoperative distention and to keep the gastrointestinal tract at rest. Such a tube can be passed in the patient's room. It should be cooled in ice and passed with no lubrication other than the ice water which adheres to its surface. The patient should be asked whether there is any impediment in one nostril or the other so that the tube can be put through the more patent of the two nostrils. When the tube reaches the patient's pharynx it may produce some gagging. At this point the patient should be instructed to swallow hard and if necessary even be given some water to drink as this will help carry the tube down the esophagus. Patients differ in their reactions to this procedure and some gag strenuously when the tube is in the pharynx. Again, if there is any suspicion that the tube has gone into the trachea, the outer end of the tube should be held next to the cheek or back of the hand to see whether expired air is issuing from it. If such is not the case and the gagging seems disproportionate to what might be expected, the pharynx should be examined by means of a flashlight to see whether or not the tube is curling up in it. If it has curled up in the pharynx, the tube should be withdrawn through the nose until the tip can just be seen above the middle of the soft palate and then the swallowing should be begun again as the tube is slowly passed. Having the patient pant or breathe rapidly through the mouth may facilitate the process. The position of the tube within the stomach can be confirmed by aspirating gastric contents. Very rarely will a tube, properly placed within the stomach, fail to yield some gastric contents. However, if it seems that the tube is in the stomach and yet nothing can be aspirated, the tube should be gently irrigated with 50 cc of water, most of which should return on aspiration.

When a tube of the Miller-Abbott type is being employed in an effort to apply suction at some point beyond the pylorus, it is important that the tube have appropriate markings on it so that the amount which has been passed into the stomach can be easily determined by glancing at the part which remains outside. When extreme difficulty is experienced in passing a tube, it may be necessary to spray the pharynx with a 2 per cent solution of cocaine, as is done before bronchoscopy.

Thoracentesis. This procedure is frequently employed. It is usually performed for the removal of fluid from a pleural effu-

SOFT TISSUE INJURIES FROM MECHANICAL FORCES

By JOHN L. BELL, M.D.

JOHN LOUIS BELL received his education at Duke and Northwestern Universities. He has devoted his special talents to the surgery of the hand and the treatment of burns and soft tissue injuries. He is an Assistant Professor of Surgery at Northwestern University. He represents the third generation of the school of surgeons, originated by Kanavel, interested in the hand.

The meticulous and thorough efforts characteristic of the surgical teachings of this group to create a closed, clean wound out of an open, dirty, destructive injury have been multiply repaid by shortening the convalescent period, restoring function more completely and decreasing economic loss for the patient.

The body is threatened constantly by accidental trauma from extrinsic forces: burns, mechanical injuries, chemical injuries, cold injuries, blast injuries and radiation injuries. In recent times there have been as many as 93,000 accidental deaths and 9,500,000 injuries annually in this country. Many of the victims are killed outright but others die during their course of hospitalization. Traffic accidents account for 33,000 deaths annually, or over one-third of the total. It should be obvious that any member of the medical profession may be called upon to render initial care to the injured.

Wounding or injury from mechanical forces is the most frequent form of trauma requiring emergency treatment. There may be no limit to the anatomic distribution of injuries, particularly in those individuals in-

jured in automobile accidents, tornadoes or other civilian disasters. These injuries often simulate the trauma of warfare. Both military and civilian authorities are aware of the potentials for mass casualties in this thermonuclear age.

All accidental injuries can be divided into *closed* or *open* wounds and the difference is determined by the integrity of the body surface. Wounds may be superficial or deep, obvious or concealed, and the tissue damage ranges from slight to the most severe.

A rational approach to the care of the injured is necessary because the deleterious effects from wounds are frequently widespread as well as local. Hemorrhage, shock due to trauma, and asphyxia produce life-threatening situations, which demand immediate treatment and take precedence over

patible with the competence and business-like performance which the patient expects in a room where his life may well be in jeopardy.

Even in conditions of extreme quiet, however, a prolonged wait may be very disturbing to the patient's peace of mind, so he should not be brought to the operating room any earlier than is necessary for expeditious handling. When he has reached the operating floor, he should not be left unattended in the corridor for any period but should be transferred immediately to the room where his operation is to be performed.

In the operating room the attending surgeon is responsible for whatever goes on. This responsibility is a moral and ethical one as well as a medicolegal one. In the last respect, it is only partially shared by the anesthesiologist and by the hospital through its salaried employees such as nurses, orderlies and other attendants. The surgeon must take full charge of all that goes on in the operating room and is completely responsible for whatever happens to the patient. Therefore, members of the house staff should do whatever tasks have been assigned to them and wait quietly for the operation to begin. It is not required of any house officer to ask the anesthetist about the patient's condition or to inquire of the scrub nurse whether certain instruments have been included. His greatest service to the surgeon lies in his readiness to do what he is told and in his ability to assist as directed in the actual operative procedure.

At the conclusion of the operation, some member of the house staff should assist the other attendants and the anesthetist in transferring the patient from the operating table to the cart and accompany the patient to his room to assist in the transfer from the cart to the bed. In the patient's room he should make certain tactfully that all members of the family are out of the room while the patient is being returned to bed and intravenous fluids and other paraphernalia are being adjusted and while he is checking the patient's vital signs. He should also check the functioning of mechanical apparatus at this time. He can render the nursing service a great help by asking that excessive quantities of flowers, magazines, cigarettes and other trivia be removed from the bedside table and other important working surfaces until the patient's convalescence has reached a point where these items do not interfere with efficient nursing care.

epithelium has regenerated. A clean abrasion heals by spontaneous epithelization from the undamaged epithelial elements and skin appendages. Infection impairs healing and at times a partial-thickness injury to the skin is converted into a whole-thickness loss.

A *laceration* is a linear wound created by either sharp instruments or blunt objects. Lacerations vary from neatly incised wounds to those with irregular, torn and contused surfaces. Damage to the skin and underlying tissues is localized to the path of the wounding agent. Contused lacerations result in some tissue loss and beveling injuries often impair the blood supply to the thinner skin flap.

A *penetrating wound* is created by a missile or object. The energy which is imparted to the tissues is dependent upon the mass and velocity of the wounding agent. Tissue damage from low-velocity missiles or instruments is confined closely to the tract of the wounding agent. The wound of entrance is usually small, but the tract may be of any depth. Pieces of skin or clothing are frequently imbedded in the wound along with the retained missile. A perforating wound occurs if the missile or instrument passes completely through the tissues and emerges at a different location. Wounds of exit are usually larger than wounds of entrance in perforating injuries from missiles. High-velocity missiles used in warfare produce penetrating wounds with extensive tissue damage beneath the surface. The external appearance of these wounds is misleading. An instantaneous but temporary cavity forms around the missile and its tract. The volume of this cavity depends more upon the velocity of the missile than its size. The energy imparted to the tissues in the creation of the temporary cavity can severely damage blood vessels, nerves and other structures at varying distances from the course of the missile. Bone fragments or shell fragments frequently act as secondary missiles and cause further and widespread tissue damage.

Avulsions are wounds characterized by the tearing of tissues from their attachments. Skin and subcutaneous tissues are either partially or completely avulsed from the underlying tissues and any degree or extent of damage to deeper structures can occur. Many flaps are so severely mangled that there is little doubt concerning their salvation. Frequently it is difficult to determine the viability of a partially avulsed flap, since gross damage to the skin, fat and blood

vessels may not be evident upon inspection. The survival of a flap is dependent largely upon the adequacy of the circulation to the part. The efficacy of venous return from the flap is a factor which determines ultimate survival of the tissue, even though the arterial supply appears to be adequate. If an obviously devitalized flap is replaced it soon becomes necrotic and infection frequently occurs.

Every combination of the various types of accidental wounds may be present in *open crushing injuries*. Damage to both the covering tissues and deeper tissues is extensive. These wounds are similar to some combat injuries. Two factors determine the severity of the compression damage—first, the area of the body involved and, second, the nature of the force and the duration of the application of pressure to the part.

First Aid. First aid is the immediate care given to the injured person at the scene of the accident. The manner in which it is performed may at times mean the difference between life and death. Frequently the services of a trained layman, much less a physician, are not immediately available. The seriously injured person should not be moved hastily or roughly. Obvious fractures have to be splinted and an attempt should be made to control external bleeding. Obstruction of the airway is an immediate threat to survival, but often the relief is as simple as turning the head to one side and pulling the tongue forward to clear the oropharynx. Sucking wounds of the chest should be securely closed by an airtight dressing.

Open wounds are contaminated at the time of injury, but further contamination can be avoided by applying a sterile or, if such is not available, a clean dressing. Antiseptics, ointments or powders should never be applied to wound surfaces because of further contamination and possible chemical injury to the tissues. Usually external bleeding from extremity wounds can be controlled by applying compression to a dressing overlying the site of injury. Elevation is helpful if it can be done without too much manipulation. Routine use of tourniquets at the accident scene is to be condemned, for the harm from improper application outweighs any possible advantage in almost every case. If venous return is impeded but arterial inflow is not stopped, bleeding from an open wound of an extremity is accentuated until the *constrictor* is removed. When a tourniquet is applied too tightly the blood supply to a limb may be jeopardized, or direct and

all other measures of care. Further trauma to the patient and to the wound itself is prevented by careful handling. An accurate history and systematic physical examination are essential to assess the patient's condition and the total reaction to trauma, as well as to evaluate the wound. For patients with multiple injuries, priority of care is established for those wounds which threaten life. The wound is treated only after a working diagnosis has been established and other decisions involved in management are made, such as the necessity and urgency for surgical intervention and the choice of anesthesia.

There is no practical all-inclusive classification for wounds or injuries. Terms differ and frequently many combinations of types are present in the same wound. However, all accidental wounds are either closed or open. It must be emphasized that the external appearance of an open wound does not indicate the extent or degree of damage to deeper tissues. Many serious closed injuries occur without early or obvious external signs or manifestations.

Closed Wounds. Closed wounds are also called nonpenetrating injuries. Any tissue may be involved even though the skin remains intact. These injuries are characterized by the crushing, tearing or rupturing of tissues and by internal hemorrhage. Contusions, ruptures and sprains are specific examples.

A *contusion* is produced by a blow to the body by a blunt force or object and there is no obvious break in the continuity of the skin. Usually the damage is confined to the subcutaneous tissues, but deeper structures may be involved, depending upon the force of the impact. The tearing of small blood vessels causes bleeding and blood infiltrates the tissues. The damage to tissues results in exudation of serum. Discoloration beneath the skin and swelling are frequent external signs in superficial contusions. If a larger blood vessel is torn, hemorrhage may be profuse and extravasated blood may form a hematoma between the layers of the tissues. The blood supply to the surrounding tissues may be jeopardized by an expanding hematoma. If the overlying skin is deprived of its blood supply, it may undergo varying degrees of destruction and lose its capacity to act as a protective barrier against infection. If swelling is excessive and confined to a rigid tissue compartment, the tissues may be injured by the effects from direct pressure. Severe contusions may lacerate underlying viscera or solid organs, particularly

in the head, neck and thoracoabdominal regions. Injuries to structures far removed from the site of the external impact are not uncommon because of two factors: inertia and the variable tissue resistance.

Ruptures of tendons, muscles and ligaments are caused by either direct or indirect violence. Muscle rupture may occur when two antagonistic groups of muscles contract violently at the same time. Ligamentous tearing is called a *sprain*. Ruptures and sprains vary from incomplete to complete disruption of the continuity of the tissues. The resulting deformity, swelling and loss of function are dependent upon the severity of the injury. Violent nonpenetrating blows may rupture hollow viscera or lacerate solid organs, particularly in the abdominal region. Serious closed injuries may occur in any region of the body.

Open Wounds. Open injuries denote a break into, or an actual loss of, the protective skin barrier. The underlying tissues are damaged to varying degrees and extent. Open wounds are contaminated by bacteria at the time of the trauma either by the wounding agent or foreign material introduced into the wound. Further contamination after injury is possible until the wound is closed.

There are many types of open wounds: *abrasions, lacerations, penetrating injuries, avulsions and open crushing injuries*. Military surgeons differentiate between high-velocity and low-velocity missile wounds. Frequently the degree of damage to deeper tissues is suspected by the nature of the trauma. In wounds involving the extremities, injuries to the nerves, muscles, tendons and blood vessels can be diagnosed by testing the function of parts distal to the site of injury. In penetrating injuries of the neck, abdomen and perineum, the ultimate extent of the injury may have to be proved by surgical exploration. No wound in any location should be probed in an attempt to establish the depth or extent of the injury. This maneuver cannot be expected to give reliable information but can cause further harm by accentuating hemorrhage and introducing further contamination.

The most superficial type of open wound is an *abrasion* which involves destruction of varying depths of the skin. Bleeding from the injured skin surface is slight and is accompanied by serum exudation. A dried crust of blood and serum usually forms within a few days and unless infection occurs, the crust should not be disturbed until the

another form of trauma and tissues must be protected from excessive operative injury. Aseptic technique, gentleness in handling tissues and meticulous hemostasis are essential to any surgical intervention.

The optimal time after injury for the initial care is within the first eight hours, which is usually considered to be the time prior to actual bacterial invasion of tissues. This interval is often called the "golden period"; however, there are many other factors which have to be considered other than an arbitrary limit of time. For example, because of an excellent blood supply most wounds of the face can be cleansed and repaired safely as long as twenty-four hours after injury. The history of the contamination, the type and location of the wound and the extent of tissue damage will influence the extent and character of the initial treatment.

The adverse effects upon wounds from the presence of devitalized tissue are impaired wound healing and local or invasive infection. Devitalized tissues soon become necrotic and provide an ideal culture medium for bacterial growth. Only living and healthy tissues can effectively combat certain degrees of bacterial contamination. It should be recognized, however, that if the number of virulent microorganisms present in any wound is excessive, infection may not be avoidable in spite of the inherent ability of living tissue to combat bacteria.

Wound Cleansing. Wound cleansing, using aseptic precautions, is an integral part of the initial treatment. Every open wound is contaminated and frequently foreign material is imbedded in the wound. For extensive wounds, preparation of the proposed operative field is performed after the patient has been anesthetized. The surrounding skin is shaved and carefully cleansed with soap or a bland detergent and sterile water, while the wound is protected by a sterile dressing. Following thorough cleansing of the skin, the wound is carefully irrigated with sterile saline solution and any loose foreign material is removed. The details of technique may vary with different surgeons, but the procedure is essentially a mechanical process with care being taken to avoid irritation of the skin or trauma to the tissues. For the least serious type of wound at least ten minutes is required. In extensive injuries, more than one change of sterile gloves and materials is required and additional time should be taken to insure the cleanest field possible.

It is necessary to prepare an area large enough to carry out the operative procedure without fear of contamination from unprepared skin surfaces, for the original wound may have to be enlarged. For wounds of the extremities the entire circumference is prepared, and in hand injuries the entire wrist and lower forearm are cleansed.

Wound Excision. Wound excision, often called débridement, is the foundation of initial operative care of open wounds and it is most effective if performed as soon as possible after the injury. Its objective is to convert the accidental wound into a surgically clean wound which contains only viable tissues with an adequate blood supply. This goal is accomplished by the removal of devitalized tissues, foreign substances and tissues which are hopelessly damaged. The extent of the procedure varies with the type of wound. For example, an incised laceration may differ little in appearance from an operative incision, but blood clots have to be removed and bleeding vessels ligated in order to prevent impaired wound healing. In such a wound little or no removal of tissue would be necessary. Avulsions, crushing injuries and penetrating wounds, particularly high-velocity missile injuries, are associated with extensive tissue destruction and require meticulous and thorough wound excision. If the nature of the injury, type and location of the wound and a working diagnosis have been established beforehand, the depth and extent of tissue damage and degree of contamination can be anticipated.

Actually, débridement or excision is an exploratory procedure which usually begins on the surface and progresses into the depths and recesses of the wound. Each type of tissue encountered is carefully assessed as to its viability or extent of damage. Blood clots and foreign bodies are removed and careful hemostasis is achieved. Knowledge of the regional anatomy is necessary to protect important structures, nerves and blood vessels from any possible operative injury. Injured structures may be distorted or blood stained and should be identified in normal tissue and traced to the site of the injury. When there is deep damage in the presence of a small external wound, additional operative exposure is attained by enlarging the original wound along physiologic lines. A decision is made to remove any tissue only after careful evaluation of its viability, for there must be no needless sacrifice of tissue. If tissue is devitalized, however, it must be

at times irreparable damage to the underlying neurovascular structures may occur. Handling the seriously injured person requires skillful and competent care. Speed and rough handling during transportation may accentuate bleeding or shock and aggravate the injury.

Definitive Care. When the injured person arrives at a location where medical services are available, a rapid survey of the situation must be made by the first physician in attendance. Any delay in the prompt recognition and immediate treatment of shock, hemorrhage or asphyxia may result in a fatality. A history of the injury should be obtained and the patient should be thoroughly examined to determine the extent of the trauma. Further injury to the patient should be prevented by careful handling during all phases of care. It is essential to establish a working diagnosis and assess the general condition of the patient before proceeding with definite treatment of local wounds.

Failure to obtain a history and perform a comprehensive physical examination leads to many errors in total management of the injured patient and his wounds. The past medical history may influence treatment: does the patient have heart disease or diabetes; is there a history of recent or prolonged steroid therapy; are there allergies or known sensitivities to drugs and serum? A history of the nature of the injury is an invaluable aid to the examiner in determining the probable locations and extent of the injuries. The history of the circumstances of the injury as to the exact time, place of the accident, and type of first-aid gives information which can be used to anticipate the degree of bacterial contamination. Careful appraisal of the information obtained from the history and examination serves as the basis for total evaluation of the patient. Only then can further care be outlined and attention focused upon local wounds.

In many cases operative intervention may be an integral part of resuscitation. The patient who has an obstructed airway may not be relieved by the simpler maneuvers and may require tracheostomy. Operative exploration to arrest continuing internal hemorrhage and closure or stabilization of chest defects to correct severe cardiorespiratory alterations are other examples. If there are multiple injuries, the wounds which are the greatest threat to life should receive priority of treatment. Some examples are those injuries due to local tissue defects which result

in asphyxia, respiratory obstruction or other serious disturbances in the cardiorespiratory function. Others include cases of massive hemorrhage, perforation of intra-abdominal viscera or organs and serious open or closed cerebral injuries.

Treatment of Closed Injuries. Operative intervention may be necessary at varying intervals after occurrence of closed injuries. Most superficial closed injuries, namely contusions, are treated by nonoperative surgical measures. For sprains and incomplete muscle tears of the extremities an efficient compression dressing, rest and elevation may be all that are necessary, however, complete ruptures of musculotendinous and ligamentous structures frequently require operative correction as soon as possible. In regions other than extremities, serious damage to underlying organs and vital structures can be obscured initially by the absence of external marks of violence and a paucity or slowness in the development of abnormal physical findings. Repeated examinations at frequent intervals are essential to determine any changes in physical findings which may indicate the necessity for emergency operation. An exploratory laparotomy is a life-saving measure to control internal hemorrhage or repair damaged intra-abdominal viscera. In any location an expanding hematoma has to be controlled to alleviate the harmful effects of pressure against tissues or organs. Established hematomas are frequently aspirated or evacuated surgically for the same reasons. Whenever the blood supply to the skin is jeopardized by uncontrolled swelling and hemorrhage in the underlying tissues, the original closed injury may be converted into an open wound by breakdown of this protective barrier.

Treatment of Open Wounds. The first objective of care in all open injuries is to convert the open contaminated wound into a surgically clean wound, which should be closed as early as circumstances permit. Operative care should not be undertaken prior to the establishment of an accurate working diagnosis and a thorough evaluation of the patient. The selection of anesthesia will depend upon the wound and the condition of the patient. When a wound is known to be superficial and local anesthesia can be employed, the initial wound treatment may be performed in a well equipped dispensary or emergency room, using the same aseptic precautions that are carried out in the operating suite. One must remember that any operative procedure is

another form of trauma and tissues must be protected from excessive operative injury. Aseptic technique, gentleness in handling tissues and meticulous hemostasis are essential to any surgical intervention.

The optimal time after injury for the initial care is within the first eight hours, which is usually considered to be the time prior to actual bacterial invasion of tissues. This interval is often called the "golden period"; however, there are many other factors which have to be considered other than an arbitrary limit of time. For example, because of an excellent blood supply most wounds of the face can be cleansed and repaired safely as long as twenty-four hours after injury. The history of the contamination, the type and location of the wound and the extent of tissue damage will influence the extent and character of the initial treatment.

The adverse effects upon wounds from the presence of devitalized tissue are impaired wound healing and local or invasive infection. Devitalized tissues soon become necrotic and provide an ideal culture medium for bacterial growth. Only living and healthy tissues can effectively combat certain degrees of bacterial contamination. It should be recognized, however, that if the number of virulent microorganisms present in any wound is excessive, infection may not be avoidable in spite of the inherent ability of living tissue to combat bacteria.

Wound Cleansing. Wound cleansing, using aseptic precautions, is an integral part of the initial treatment. Every open wound is contaminated and frequently foreign material is imbedded in the wound. For extensive wounds, preparation of the proposed operative field is performed after the patient has been anesthetized. The surrounding skin is shaved and carefully cleansed with soap or a bland detergent and sterile water, while the wound is protected by a sterile dressing. Following thorough cleansing of the skin, the wound is carefully irrigated with sterile saline solution and any loose foreign material is removed. The details of technique may vary with different surgeons, but the procedure is essentially a mechanical process with care being taken to avoid irritation of the skin or trauma to the tissues. For the least serious type of wound at least ten minutes is required. In extensive injuries, more than one change of sterile gloves and materials is required and additional time should be taken to insure the cleanest field possible.

It is necessary to prepare an area large enough to carry out the operative procedure without fear of contamination from unprepared skin surfaces, for the original wound may have to be enlarged. For wounds of the extremities the entire circumference is prepared, and in hand injuries the entire wrist and lower forearm are cleansed.

Wound Excision. Wound excision, often called *débridement*, is the foundation of initial operative care of open wounds and it is most effective if performed as soon as possible after the injury. Its objective is to convert the accidental wound into a surgically clean wound which contains only viable tissues with an adequate blood supply. This goal is accomplished by the removal of devitalized tissues, foreign substances and tissues which are hopelessly damaged. The extent of the procedure varies with the type of wound. For example, an incised laceration may differ little in appearance from an operative incision, but blood clots have to be removed and bleeding vessels ligated in order to prevent impaired wound healing. In such a wound little or no removal of tissue would be necessary. Avulsions, crushing injuries and penetrating wounds, particularly high-velocity missile injuries, are associated with extensive tissue destruction and require meticulous and thorough wound excision. If the nature of the injury, type and location of the wound and a working diagnosis have been established beforehand, the depth and extent of tissue damage and degree of contamination can be anticipated.

Actually, *débridement* or excision is an exploratory procedure which usually begins on the surface and progresses into the depths and recesses of the wound. Each type of tissue encountered is carefully assessed as to its viability or extent of damage. Blood clots and foreign bodies are removed and careful hemostasis is achieved. Knowledge of the regional anatomy is necessary to protect important structures, nerves and blood vessels from any possible operative injury. Injured structures may be distorted or blood stained and should be identified in normal tissue and traced to the site of the injury. When there is deep damage in the presence of a small external wound, additional operative exposure is attained by enlarging the original wound along physiologic lines. A decision is made to remove any tissue only after careful evaluation of its viability, for *there must be no needless sacrifice of tissue*. If tissue is devitalized, however, it must be

removed, regardless of the resulting defect. The greatest problem may be to appraise correctly tissues which have been injured but remain attached and are not obviously devitalized.

An assessment of the viability of skin may be difficult at times. In most sharp lacerations there is little destruction of skin, but in avulsing and crushing injuries the damage is often extensive. Viable skin bleeds actively from its cut surface and when gentle pressure is applied it blanches temporarily. The rapidity of the return to normal color should be observed. One can compare and test the skin in question with that in locations distant from the site of injury. The flap that does not have a correct color is usually devitalized or destined to become necrotic. One must never save skin flaps that are severely crushed, whose vessels are thrombosed, or which are deprived of an adequate blood supply. Although the color may appear normal at the time of the operation, if venous return is impeded the flap may die. Skin on the scalp and face has an excellent blood supply and rarely requires radical excision. Every effort should be made to save all viable skin on the palmar surface of the hand and the plantar aspects of the feet.

Muscle viability is determined by inspection and testing its properties. Viable muscle is red, its surface bleeds briskly and it contracts when touched or stimulated. Dark, soft muscle suffused with blood is usually devitalized. Massive damage to major muscle groups produces harmful by-products which are absorbed into the blood stream and may lead to deep shock. Nonviable muscle is an excellent culture medium for bacterial growth, particularly of anaerobic organisms.

Fascia withstands trauma well and only jagged edges need be excised. Fasciotomy, however, may be necessary to relieve pressure on underlying tissues within tight fascial compartments.

Tendons should not be excised unless there is extensive fraying or soiling from foreign material.

Nerves have an excellent blood supply and excision should always be minimal, for even a severely contused nerve may retain some function or be repairable.

Major blood vessels should be carefully evaluated before ligation is considered. Repair or anastomosis may be possible. Torn or divided smaller blood vessels in distal

portions of the extremities can usually be ligated without jeopardy to the blood supply of the part.

If excision has been properly performed, further steps toward repair and closure are possible in the majority of wounds sustained in civil life. In situations involving mass casualties or in wartime combat injuries, the initial operative procedure should terminate after excision and correction of life-threatening defects in the wound.

Wound Closure. The goal of initial surgery is to obtain a clean, closed wound which will heal by primary intention, but unless a wound has been properly cleansed and excised, primary wound closure will result in impaired healing or infection. With proper excision, most civilian injuries can be closed primarily if the time interval or degree of contamination has not been excessive. Healing of the depths can be no better than healing of the surfaces. An example is an avulsing injury of the hand with a skin flap overlying tendon repair. If the flap fails to survive, the tendons soon become exposed and necrosis and infection ensue.

There are many ways to close accidental wounds. Many wounds may be closed by suture alone, provided that there has been no great loss of skin. No wound should be closed with undue tension on the tissues. Tension causes strangulation of tissues and necrosis of wound edges eventually occurs. Healing is impaired and a pathway for bacteria is opened to the underlying structures. If the skin does not approximate without tension, undermining the subcutaneous tissues may allow sufficient relaxation to permit proper closure. This is applicable to face and neck wounds and other areas where there is laxity of the tissues. Another method for skin closure is the use of a relaxing incision with undermining to permit local shifting of skin and subcutaneous tissue. More extensive local shifts of adjacent tissues are called rotation flaps.

If the skin defect is too large to be closed by suture alone or local shifts of tissues, a skin graft may be applied. Skin grafts are of two types: the split-, or partial-thickness, and the whole-thickness graft. These are called free skin grafts because either type of graft is obtained by detaching it completely from the body surface and transplanting it to another location. The donor area of split grafts contains sufficient epithelial elements to allow spontaneous epithelization of this newly created wound which is similar to a

superficial abrasion. A whole-thickness graft donor site leaves a wound completely devoid of skin and this wound has to be closed. It is possible to close small areas by undermining and suture, but a donor defect which is too large may require application of a split-thickness graft. The split-thickness skin graft is used frequently in primary procedures to cover large defects. Full-thickness skin grafts are more difficult to apply and are not as useful in the initial care.

Another method to provide covering tissue is the use of a pedicle flap, which consists of skin and its attached subcutaneous tissue having an adequate circulation. Pedicle flaps are used to cover exposed tendons, nerves, bones and joints when there is no areolar tissue or skin locally which can be shifted to cover these structures. Pedicles are transferred from one part of the body to another with an intact blood supply. The proximal portion of the flap has to remain attached at its site of origin for several weeks until a new blood supply from the recipient area can grow into the transferred tissue. When adequate circulation has developed in the flap from the recipient area, it is then detached from its donor site at a secondary operation.

Although every open wound, if not grossly infected, should be cleansed and excised, there are many factors which determine the necessity or advisability for deep repair and surface closure. The location and extent of the injury and the condition of the patient as well as the degrees of contamination are basic considerations. The extent to which deep repair and closure can or should be carried out is a matter of both knowledge and judgment. In wounds of the abdomen, repair of injured viscera is essential for survival. Open joint capsules are repaired to prevent infection in joints. Sucking from the chest must be closed with muscle flaps even though the skin may be left open for later closure. In brain injuries, primary closure of the dura mater and scalp is necessary to avoid infection, herniation and fistula formation. Exposed tendons, nerves and bone have to be covered with muscle or areolar tissue to prevent maceration and eventual necrosis.

In some situations the skin is closed primarily and repair of deeper structures is either minimal or is postponed completely until the wound is well healed. Although this may necessitate a secondary operation at a later date, the chances for optimal recov-

ery of function may depend upon this decision.

The management of wounds sustained in warfare and some civil disasters requires staging of the operative procedures. These wounds are cleansed and excised initially, but closure is delayed until it is certain that the danger of wound infection has passed. Exceptions to this policy are wounds of the face and scalp, which are closed at the time of the initial procedure. Some hand injuries are partially or completely closed to protect the underlying structures. After débridement the wound is covered by a compression dressing and the injured part is immobilized. Within three to seven days, if the wound reveals no evidence of gross infection and the tissues appear healthy, the wound may be closed. This second procedure is called *delayed primary closure* by most military surgeons but is often referred to as *secondary*, or *delayed*, *suture*. Reconstruction or reparative surgery is undertaken at a later date when the tissues are healed soundly and the patient's condition is well stabilized.

Healing of all wounds is assisted by rest. In extremity and facial wounds, resilient compression dressings help to minimize edema, obliterate dead spaces and provide rest. Injured extremities should be immobilized by splints, well-padded plaster molds or bivalved casts. Some degree of swelling is a natural response to injury, but if it can be minimized the tissues will heal more kindly. Elevation promotes more adequate lymphatic and venous return from extremities. Swelling may, however, be accentuated by constrictive dressings to such a degree that the blood supply to a part is compromised. Local pressure necrosis can be avoided by adequate padding over bony prominences.

Prophylaxis against tetanus is an important consideration in every person who has sustained an open injury. A tetanus toxoid booster is given when there is a definite history of previous active immunization. Tetanus antitoxin provides temporary, passive immunization but should be given with caution by proper testing for sensitivity. Even then, serious delayed reactions to the serum may occur.

The value of antibiotics is undoubted, but they are not always needed. Their use should be restricted to cases in which specific indications exist, such as gross contamination, extensive tissue destruction or inoculation

of the wound with highly virulent bacteria. Adequate, early wound surgery is the best protection against infection.

SHOCK

By ISIDOR S. RAVDIN, M.D.,
and JAMES E. ECKENHOFF, M.D.

ISIDOR SCHWANER RAVDIN, John Rhea Barton Professor of Surgery at the University of Pennsylvania, is a Hoosier by birth. He was educated at Indiana University and the University of Pennsylvania. He has directed the Harrison Laboratory of Surgical Research from which have come many fundamental contributions to surgery. Consultant in Surgery in the Far East during World War II, Dr. Ravdin has played an active role as a member of the Armed Forces Medical Policy Council of the Department of the Defense and has an intimate knowledge of the most recent developments in the field of surgery with which this chapter deals.

JAMES EDWARD ECKENHOFF, of Maryland, was educated at the University of Kentucky and received his medical training at the University of Pennsylvania. Actively interested in problems of research relating to the field of anesthesiology, he serves as Professor of Anesthesiology at the University of Pennsylvania.

Shock is a common clinical entity, extensively studied for over a half a century, yet the basic mechanisms are still incompletely understood. Shock is usually envisioned as accompanying or following trauma; indeed, a great impetus for its study has been the relatively concentrated mass wounding accompanying war. However, the syndrome is not confined to trauma or to surgery but is frequently seen in conjunction with medical, neurologic and even psychiatric disorders. This implies extensive ramifications of the etiologic processes of shock and casts doubt upon a single exciting cause.

Shock has been variously qualified, e.g., surgical shock, wound shock, hemorrhagic shock, neurogenic shock. Such terms are likely to refer to probable initiating causes. However, the clinical picture is essentially

the same under all of these conditions. Therefore, the only qualifications of shock we shall use will be *impending shock* and *irreversible shock*. The first qualification implies that the patient does not appear to be in shock but does demonstrate signs and symptoms suggesting that shock will occur within a short time unless preventive steps are taken. When the symptoms of shock have persisted sufficiently long to preclude recovery in spite of therapy, irreversible shock has occurred. The period required to produce irreversibility is variable; shock in the patient in poor physical condition may become irreversible within minutes. In a usually healthy but recently injured young adult, irreversible shock may not appear for hours.

The clinical picture of shock is so well

known and widely taught that even the twelve-year-old Boy Scout can describe it reasonably accurately. The patient's skin is pale, cold and moist. Respirations are shallow, rapid and often grunting in character. However, in profound shock, respirations may be only two to three per minute. Occasionally the lips and fingernails are slightly cyanotic. The pulse is weak and rapid. The blood pressure is low. Urine formation is scanty or absent. Thirst is a common feature. Complaints of pain may be absent except when the patient is moved. Apprehension and restlessness are usually displayed. The sensorium may be clouded.

ETIOLOGY

Some exciting factors of shock are fairly clear. The most obvious and most common is acute hemorrhage or protracted fluid loss. The early mechanisms of shock following trauma without blood loss, neurogenic shock coming on after cranial injury, cardiogenic shock preceded by myocardial infarction, or shock occurring from toxicity or poisoning are not clearly understood. Least well explained is why shock develops into irreversibility.

Originally attempts were made to imphicate a single factor in the development of irreversible shock. Early theories suggested that the major defect was inadequate cardiac output, prolonged maintenance of hypotension because of regional vasodilatation, a reduced blood volume due to leakage of fluid from the blood vessels, or vascular depression produced by toxic material released from wounds. The consensus today appears to be that no one factor predominates but that many things contribute to produce circulatory insufficiency following which irreversibility occurs.

Freeman has presented this chain of

events diagrammatically as shown in Figure 1.

The circulatory response to stress should be understood for orientation in a discussion of the etiology of shock. Table 1 is a modified version of Bazett's calculation of the distribution of the circulation in man and the uptake of oxygen by organ systems. It is apparent that, under normal conditions, the major demand for blood flow and oxygen uptake is by vital organs (brain, heart and hepatic portal system), yet these represent only 7 per cent of the total body weight. On the other hand, the principal mass of the body (skeletal muscle, connective tissue, bone and skin), representing 93 per cent of the total weight, receives only 30 per cent of the cardiac output and 40 per cent of the oxygen intake (Table 2).

Under conditions of stress, widespread changes occur in blood volume distribution. With muscular exercise, blood flow to muscle increases as does oxygen consumption. Such changes are met by diminution in flow to other tissues, notably the kidney. These are normal reflex mechanisms.

Following hemorrhage, blood flow to vital organs is maintained at the expense of the principal mass of body tissue. Initially, blood pressure is supported by generalized peripheral vasoconstriction which simultaneously diverts blood from the peripheral circulatory beds (e.g., muscle, skin) to vital organs. Kidney blood flow diminishes most sharply and with the slightest stress—even with emotion. As blood volume is reduced by hemorrhage, blood flow through nonvital tissue is gradually reduced by increasing vasoconstriction until finally a peak of compensation may be reached when the functional circulation consists solely of blood flow to and from the brain, heart and liver. Evidence suggests that finally even the liver may be shunted

Figure 1 Diagrammatic representation of chain of events contributing to the production of inadequate circulation following which irreversible shock can occur.

Table 1. Regional Blood Flow and Oxygen Consumption

REGION	WEIGHT (KG.)	PERCENTAGE OF TOTAL WT.	ORGAN BLOOD FLOW (CC./MIN.)	CARDIAC OUTPUT (%)	ORGAN OXYGEN UPTAKE (CC./MIN.)	TOTAL OXYGEN UPTAKE (%)
Brain	1.4	2.2	750	13.9	46.2	22.9
Heart	0.3	0.5	255	4.7	29.1	11.6
Hepatic-portal	2.6	4.1	1500	27.8	51.0	20.4
Kidney	0.3	0.5	1260	23.3	17.6	5.0
Skeletal muscle	31.0	49.2	840	15.6	49.6	20.0
Skin	3.6	5.7	460	8.4	10.9	4.8
Residual tissue	23.8	37.8	380	6.4	50.0	15.3

out of the circulation and all blood flow from the inferior vena cava ceases, yet with flow in the superior vena cava persisting. This implies that under these conditions, the brain continues to be supplied with blood.

The common denominator of irreversible shock is a reduced effective blood volume. In hemorrhage, the factor responsible for the reduction is clear, but when major hemorrhage is absent, the cause of hypovolemia is obscure. While the total amount of blood within the body may be unchanged, the volume circulating can be reduced by leakage or sequestration—thus the effective blood volume becomes inadequate.

Formerly it was believed that, in the absence of significant hemorrhage, blood volume was reduced by "leakage" of fluid from blood vessels into tissue. Blalock and his associates were the first to prove that leakage need not occur for hypovolemia to appear in shock. More recent evidence indicates that blood may become trapped within peripheral blood vessels or liver and thus become "lost" to the circulation so far as the prime purpose of circulating blood is concerned—transportation of oxygen, foodstuffs and metabolic products. The first sign of slowing blood flow and impending shock at operation may be increasing venous oxygen desaturation. This may occur despite a satisfactorily maintained blood pressure or pulse and without evidence of reduced arterial oxygen concentration. It signifies that blood is passing through

capillaries so slowly that a greater than normal amount of oxygen is being withdrawn from it. It also suggests marked arteriolar compensation in order to maintain blood pressure.

Zweifach and his associates have demonstrated the activity of precapillary arterioles, capillaries and venules in the rat mesentery during normal conditions and in hemorrhagic shock. Normally all capillaries do not function simultaneously, but with stress every channel can open, tremendously increasing the capacity for blood. As blood flow slows, these vessels become engorged with blood, flow finally ceases and in some areas the capillary bed is by-passed, trapping or "sequestering" significant quantities of blood. This removes blood contained within the circulation from the "effective" blood volume. It must be remembered, however, that the applicability of these observations to all capillary beds has not been proved.

There are no studies to indicate even the approximate amount of blood that can be contained within vascular beds whose tone and reactivity have been abolished. Plethysmographic studies have indicated that simple warming of the legs can increase the volume of blood within these parts by 500 cc. or more. Investigations upon wounded soldiers in shock have demonstrated the need for infusion of vast quantities of blood in order to maintain blood pressure. In Korea, it was not uncommon to administer

Table 2. Comparison of Regional Blood Flow and Oxygen Consumption to Vital Organs and Other Tissue

REGION	WEIGHT (KG.)	PERCENTAGE OF TOTAL WT.	ORGAN BLOOD FLOW (CC./MIN.)	CARDIAC OUTPUT (%)	ORGAN OXYGEN UPTAKE (CC./MIN.)	TOTAL OXYGEN UPTAKE (%)
Vital organs (excluding kidney)	4.3	6.8	2506	46.4	126.3	54.9
Other tissue	58.4	92.7	1680	30.4	110.5	40.1

twice the patient's normal blood volume even though there was no longer evidence of active bleeding. Attempts to locate large volumes of sequestered blood by means of chromium-tagged red cells or by means of the Evans blue dye technique have failed, but the evidence is far from conclusive. Chromium-tagged red cells may be rapidly destroyed. Also, the tagged cells or dye may be unable to reach the sequestered blood, thus preventing complete dilution. Evidence in favor of sequestering was obtained from postmortem studies of men who died in shock in spite of massive transfusion. These studies revealed skeletal muscle, liver and lungs choked with blood.

Obviously, the factors mentioned all work in the same direction, namely production of an inadequate circulation. The lowered blood volume leads to decreased cardiac output. Sequestered blood and diminished capillary blood flow lower venous pressure and diminish venous return which likewise contributes to a reduced cardiac output. With prolonged hypotension, Wiggers found that the myocardium itself may be damaged and, even though the blood volume be restored, the myocardium is unable to recover. Myocardial failure then relentlessly progresses to death.

There are other factors which play a part in the progressive decline of the circulation, but their exact role has not been defined. Several lines of investigation have been followed, some of which are challenging. These include.

The balance between VEM (vasoexcitator material) and VDM (vasodepressor material). Shorr and his coworkers have demonstrated the existence of a vasoexcitator principle elaborated by the kidney and appearing in the blood stream following renal hypoxia. VEM seems to be integrated with adrenal cortical and sympathetic nervous system activity. It appears following hemorrhage or in impending shock. During this phase, VDM identified as ferritin and formed in the liver also appears, but under aerobic conditions the liver transforms it into an inactive form. With deterioration of the hepatic blood supply, oxygen lack occurs, the transformation of VDM fails and it appears in the systemic circulation. Experimentally, in irreversible shock, VDM has been detected in large quantities. However, blood samples withdrawn from Korean casualties in shock have failed consistently to yield ferritin in significant quantities.

Bacterial factor. Fine and his associates

have observed that in dogs treated with antibiotics prior to hemorrhagic shock, the survival rate was higher than in untreated, shocked dogs. They have postulated that, during shock, bacteria flourish and by either direct action or by toxic metabolites produce circulatory changes leading to irreversible shock. Antibiotics minimize and prevent this action. The antibiotics are more effective orally than parenterally, presumably because of the influence upon the intestinal bacterial flora. Likewise, some antibiotics are more effective upon organisms of the intestinal flora than are others.

There is evidence that the ability of antibiotics to prevent irreversible shock may be principally a species effect. The tissue of many animals (rat, cat, dog) are not sterile, whereas those of man, except for the gastrointestinal tract, are. Factors preventing the growth of bacteria already located in tissue may not be significant when applied to species whose tissues are not contaminated. Nevertheless the bacterial factor may be important in certain types of shock in man, such as that accompanying peritonitis, burns and massive tissue destruction. It seems more difficult to implicate the factor in cardiocirculatory or neurogenic shock.

Autonomic blocking agents. Evidence has accumulated to show that certain of the autonomic blocking agents are of value in preventing or retarding the onset of irreversible shock in animals. Among the foremost of these agents are chlorpromazine, Dibenzylamine and hexamethonium. Atropine has generally been ineffective. All of these drugs are protective if given prior to exposure to traumatic (drum) or hemorrhagic shock but are ineffective if administered after trauma has been inflicted or shock has developed. The theory of the use of autonomic blocking agents is based on the fact that during shock vasoconstriction occurs. Because of this, capillary circulation is reduced, tissue perfusion becomes inadequate, anoxic damage occurs, vessel reactivity is lost and, finally, blood is sequestered within capillaries. If vasoconstriction could be minimized or prevented by the use of autonomic blocking agents, tissue perfusion could be maintained even though arterial pressure is lowered.

So long as the blood volume is maintained within reasonable limits, the theory is feasible. It is common to see patients with lowered blood pressure without vasoconstriction who experience little difficulty. The recent use of hypotensive anesthetic tech-

niques has even popularized this entity. However, if vasodilatation occurs in the patient who has lost considerable blood without replacement, the circulatory beds in skin and muscle are kept patent at the expense of the circulation in the vital organs. As a consequence, cardiac, cerebral, hepatic and renal complications may develop earlier and with more disastrous results.

The influence of metabolites. In the early phases of shock, metabolites do not appear to play a part in the development of irreversibility. The metabolic derangements are principally those which follow progressive tissue anoxia. As irreversibility develops, however, the accumulation of metabolites may assume a more important role. An interesting field of investigation in this regard concerns the importance of rising blood ammonia levels. Experimentally, it has been demonstrated there is an increased production of ammonia in the kidneys and intestines in shock. The liver loses its ability to utilize the ammonia to synthesize urea, presumably because of hypoxic parenchymal damage. As a result, blood ammonia rises significantly. Efforts are being made at present to evaluate the significance of this observation.

Role of the adrenal cortex. The liberation of adrenal cortical steroids is one of the mechanisms by which homeostasis is maintained. In the absence of the adrenal cortex or when adrenal cortical reserves are limited, the response of the vascular system to stress such as shock may be minimal. Under such conditions the administration of adrenal cortical steroids may replenish the depleted stores and restore the reactivity of blood vessels to *l*-norepinephrine and possibly epinephrine. The importance of this factor has not been completely evaluated. In the usually healthy individual who is suddenly wounded and develops shock, the adrenal cortical response has usually been found to be normal. On the other hand, adequate data have been obtained from the chronically ill individual to indicate a diminished adrenal corticosteroid level. In these people the circulatory response to shock is often poor but may be improved by the intravenous injection of corticosteroids.

It is apparent that considerable recent interest has been directed toward the liver and its relationship to irreversible shock. While the liver may not be of much importance in the early phases of shock, as hypotension, hypovolemia and hypoxia become manifest, significant metabolic alterations

occur as a result of these influences upon the liver. These metabolic changes may be the principal factor determining irreversibility. There is experimental evidence that death from shock can be prevented by circulation of oxygenated blood through the liver.

One might summarize the factors underlying shock by saying that circulatory homeostasis is dependent upon many and varied factors (1) the pump (heart) must be adequate; (2) the blood vessels must be patent and reactive; (3) the lungs must be functional and oxygen supply sufficient; (4) there must be sufficient blood to circulate; (5) the center controlling nervous impulses (brain) must be performing satisfactorily; (6) the addition of vital substances to the blood stream must be optimal, and the mechanisms to alter metabolic products and to eliminate waste substances must be functioning satisfactorily. Interference with the aforementioned system at any point reduces the ability of the body to withstand shock and hastens the onset of irreversibility. Some factors are more important than others. For instance, the patient with a sudden myocardial infarction suffers acute injury to the pump and as a consequence may go into shock rapidly. Other factors may be of less immediate importance but may ultimately lead to shock.

THE TREATMENT OF SHOCK

Prevention. Obviously the most important factor in the treatment of shock is its prevention. This is not always possible in shock that follows sudden myocardial infarction or that appearing after cranial injury. However, much can be done to prevent shock accompanying trauma, operations, infections and burns.

The idea of anticipating the possibilities of wound shock in soldiers by the routine preventive use of chlorpromazine is intriguing. If chlorpromazine had no undesirable side effects, this use might be feasible. However, the drug is a depressant in its own right and a decrease in mental acuity in all soldiers might counterbalance the possibilities of protection from shock in a few. Nevertheless, in civilian surgical practice, the use of chlorpromazine preoperatively in patients in whom significant blood loss is expected may be worth while. The value of such protection awaits further study.

The movement of wounded, acutely ill, unconscious or anesthetized patients must be accomplished with great care. If shock is

apparent, it is better to postpone movement than to jeopardize the patient's life. Unnecessary or rough movement may produce sudden, severe hypotension or even cardiac arrest under these circumstances. The same caution should apply to movement of any unconscious or anesthetized patient. Hypotension is often seen following transferral of these patients from operating table to litter or bed. When movement is accomplished, it should be after broken bones have been splinted or properly supported. Pain, however, is not the sole cause of hypotension, as is evident from the fact that the blood pressure of anesthetized patients falls with movement. The answer appears to lie in loss of vasomotor control.

Patients with trauma may not require opiates for comfort. A relatively small proportion of men severely wounded in combat complain of pain, and pain should be the indication for the use of narcotics. These agents depress the reflex control of the circulation. In shock, impending shock or situations in which surgical shock may occur, circulatory reflexes should be functioning maximally. When opiates must be used for pain in shock, they should be injected intravenously in small doses. Drugs injected subcutaneously or intramuscularly may not be absorbed by the blood stream because of the inadequate circulation.

The principal means of preventing shock is to keep the blood volume within normal limits. All patients who have been injured and in whom shock may occur, those undergoing major surgery and those first seen in shock should have intravenous infusions. Great care and foresight must be used in the placement of intravenous needles or canulae. These must be of a size adequate to allow infusion of large quantities of blood within short periods. Effort must not be wasted in persistent attempts at venipuncture in patients in impending shock. The vein should be exposed surgically and cannulated under direct vision. Both surgeons and anesthesiologists should be facile in performing these operations. The largest stores of blood or plasma expanders are of little consequence unless the means for getting the material into the patient are available. In Korea, it was necessary to infuse as much as 4500 cc. of blood within a thirty-five-minute period in order to keep alive a patient in shock. In severe shock or when major hemorrhage is expected, more than one intravenous route should be provided so that

the required amount of blood can be administered.

Surgeons and anesthesiologists should become more skilled in estimating blood loss. In major surgical procedures associated with considerable blood loss, the "dry sponge" technique should be used. In this method, the dry weight of the sponge is subtracted from the blood-soaked weight, the difference in grams approximating the amount of blood in cubic centimeters contained in the sponge. While not completely accurate, it can be used as a suitable index for blood replacement.

Careful preparation of patients for operation will minimize the occurrence of shock in the operating room. Blood volume studies are useful, particularly in the elderly, sedentary or chronically ill patient who is to have a major operative procedure. Often these groups will be found to have significant hypovolemia. Transfusion prior to operation under these circumstances may prevent or minimize the onset of shock.

One cannot be dogmatic about the amount of blood loss tolerated without need for replacement. The healthy adult can lose 500 cc. to 800 cc. of blood without need for replacement. The elderly or acutely ill patient may not tolerate such loss. The need for blood replacement is usually indicated by the appearance of hypotension with tachycardia. However, neither of these symptoms need appear. In general, if the loss exceeds 500 cc., replacement is indicated, either with a plasma expander or with whole blood. If the loss exceeds 1000 cc., whole blood replacement of at least 500 cc. is probably indicated. It is not the province of this discussion to consider the indications for plasma expanders versus blood. The patient in shock needs blood and there may be little usefulness for plasma expanders. In the maintenance of blood volume by replacement of minor blood loss, however, they have value. Constant watchfulness by the surgeon and anesthesiologist with particular attention to fluid replacement will do much to prevent surgical or hemorrhagic shock.

Shock may be averted following sudden hemorrhage by elevating the patient's legs. The amount of blood estimated to be returned to the systemic circulation by this maneuver may equal or exceed 500 cc. However, if vasoconstriction has previously existed to a significant degree, little blood may be contained in the extremities, and elevation of the legs, therefore, may be of little

value. It has generally been assumed that the optimal position for the patient with hypotension or impending shock is a slightly head-down position. This facilitates venous return and may improve circulation to the brain. Data to support this belief are lacking.

Conversely, caution should be exercised when, after a patient has been operated upon in the lithotomy position, the legs are put down. Often this is accompanied by a precipitous fall in blood pressure due to filling of peripheral vascular channels. This can be minimized by wrapping the legs with elastic bandages prior to lowering the legs.

Hypoxic damage may be averted or minimized in impending shock if the oxygen supplies to the body are increased. This can be accomplished by increasing the oxygen concentration of the inspired gas either by means of a nasal catheter or by a mask. The former method, with the catheter at the tip of the epiglottis and with an oxygen flow of 6 liters per minute, will insure an oxygen concentration in the inspired air of about 40 to 45 per cent. The latter method, if properly applied, will supply 90 to 100 per cent oxygen. The circulation time becomes slower as the blood volume is reduced. The closer a patient approaches a shock state, the more completely his blood is desaturated of oxygen following its passage through the capillaries. Therefore, the greater the oxygen concentration in the arterial blood, the more is available to tissues. All hypotensive patients, whether in shock or not, should be given oxygen for this reason.

In patients who have had chronic illnesses or those who have shown signs of adrenal insufficiency and in whom major surgery is contemplated, adrenal cortical extracts may be of value for preoperative preparation. This may improve the response of the circulation to endogenous *l*-norepinephrine or epinephrine and to stress in general. It may also prevent the appearance of shock.

Careful anesthetic management will minimize the occurrence of shock. Prolonged deep planes of anesthesia predispose to shock, particularly if anesthesia is accompanied by rough surgical manipulation and fluid loss. General anesthetics are myocardial depressants, the degree of depression being directly proportional to the concentration of anesthetic. Diethyl ether and cyclopropane cause a liberation of norepinephrine in the body, thus preventing the appearance of the depressant effect. If catechol amine stores are exhausted, myocardial depression may be more apparent, depending upon the

depth of anesthesia. The depth of anesthesia should never exceed that needed to produce satisfactory operating conditions.

Treatment of Shock. The principles of the immediate treatment of existing shock center around a few essentials. These are:

Intravenous administration of blood. This should be given rapidly and continuously until the blood pressure returns within normal limits and the symptoms of shock abate. There is considerable disagreement concerning the value of intra-arterial versus intravenous transfusions of blood. The proponents of intra-arterial transfusion argue that blood is placed in the best position to enhance coronary and cerebral blood flow and, in general, to raise arterial blood pressure. In practice, however, one should realize that not more than 100 cc. of blood per minute can be pumped through an intra-arterial cannula, whereas the heart ejects up to 5000 cc. per minute. In shock, cardiac output and venous return are low. Therefore, there may be greater advantages in infusing large volumes of blood into the veins.

In usually healthy adults in shock there is little danger of overtransfusion and production of pulmonary edema. However, in the elderly or chronically ill patient, the possibility is greater. In general, if the blood pressure remains low, it is safe to infuse blood at a rapid rate until the blood pressure has returned to physiologic levels. The infusion should then be continued at a slower rate.

Plasma expanders should be used in the absence of blood or while blood is being crossmatched. However, it is unlikely that shock can be satisfactorily treated without blood.

Oxygen. A high concentration of oxygen should be administered. As mentioned previously, a nasal catheter with a flow of 6 liters of oxygen per minute will produce a 40 to 45 per cent concentration in the inspired air. A bag and mask if properly arranged with a high flow rate will insure nearly 100 per cent. The latter concentration is desirable in treating shock, although the mask is more uncomfortable to the patient.

Position. A slightly head-down position is probably most beneficial to the patient. If the tilt is too great, the patient's respiration may be compromised by the abdominal organs pushing the diaphragm upward, reducing tidal exchange.

It is not necessary nor is it wise to apply heat to the patient's body during treatment. This dilates cutaneous blood vessels and may

interfere with maintenance of essential circulation. As blood volume is replaced, surface warming can be accomplished gradually. Hypothermia has been advocated for the treatment of patients in shock. At present, there are few data to support this contention. Published work suggests that hypothermia alone is of no greater benefit than is chlorpromazine alone.

Vasopressor drugs. Previously it was believed that vasopressor drugs had no place in the therapy of shock. There is evidence now, however, that pressor drugs may be of value as a temporary expedient combined with the simultaneous administration of blood. The theory of the use of vasopressors is to produce vascular constriction to accommodate the reduced blood volume. As the blood volume is increased, the need for pressor drug should be reduced.

The ideal drugs for this use would be those with maximal peripheral constrictor effect and minimal cardiac or cerebral stimulant action. The most potent agent meeting these requirements is *l*-norepinephrine. This drug is a powerful peripheral vasoconstrictor which reduces the size of the peripheral circulatory bed, raises the blood pressure and facilitates venous return. It also has a myocardial stimulant effect. *l*-Norepinephrine may produce an effect when all other drugs have failed. Vasopressor therapy is not a substitute for blood replacement in most patients in shock, but it should be considered a stopgap measure to be used along with blood. Attempts should be made to withdraw support by pressor drugs as soon as a reasonable blood pressure can be maintained. Patients in shock of myocardial origin may require vasopressor therapy without transfusion.

The usual method for administering *l*-norepinephrine is to dilute 4 mg. of the drug in 1 liter of saline or glucose. This concentration can be increased at will. Its effect is manifest within seconds after beginning the intravenous infusion and disappears within minutes of termination. The rate of flow must be carefully regulated to keep the blood pressure at the desired level. One must be certain that the injection is intravenous and not paravenous, since the latter may result in tissue slough. This appears most commonly after injection into the veins of the lower limbs, but it has been observed in the arms. It can be prevented by the addition of phentolamine to the infusion. One should never inject *l*-norepinephrine intra-arterially.

When is the patient who is in shock or who has been in shock ready for operation? There are no definitive tests to suggest the patient's ability to withstand operation after he has been in shock or while he is in shock. A recently advocated test is one wherein the patient thought to be ready for operation is tilted in the head-up position for five minutes. If the blood pressure remains stable, the patient is more likely to withstand operation well. However, if the patient becomes hypotensive with the tilt, further preparation is necessary.

Another suggested test is to inject intravenously a small amount of epinephrine or *l*-norepinephrine and observe the response of the patient's blood pressure. If there is no elevation in blood pressure, the patient is probably not ready for operation. If his blood pressure rises satisfactorily, he should withstand operation.

What are the problems of management of these patients during operation? A severely wounded patient or a patient in shock or impending shock, anesthetized by an inadequately trained technician and operated upon by a surgeon of limited experience has a greater chance of dying during operation than would the same individual in the hands of an experienced anesthesiologist and surgeon. Too often the problems of anesthesia and surgery for patients in shock are learned by sad experience rather than from firsthand instruction from physicians who have already learned the fundamentals of treating patients in shock. This has been particularly true in times of war.

The problems of management can be divided into those pertaining to anesthesia and those relating to surgery. For the former, the following facts are of especial significance. Narcotics should be omitted preanesthetically since they may predispose to further hypotension. There are abundant data showing that narcotics cause respiratory and circulatory depression. Under conditions of stress, it would be desirable to avoid such depression and to have the circulatory system at peak reactivity. There is little need for narcotics and the hazards following their use are great.

An anesthetist must be aware that minimal amounts of anesthetic agents are required for patients in shock. In this condition, the circulation to the major portion of the body is absent or minimal. Therefore, the brain and other vital organs receive most of the administered anesthetic agents. It is apparent why an overdose of anesthetic

agent readily occurs. Patients who have been in shock, or are in shock, may not tolerate any anesthetic. Occasionally, even the mildest and most expertly administered anesthetic will convert shock to irreversible shock or death. In our opinion, cyclopropane is probably the anesthetic agent of choice for patients in shock. Recent work suggests that ether is to be avoided. Thiopental has likewise been incriminated for its depressant qualities in the severely ill or wounded. Muscle relaxants are rarely needed in the shocked patient. Whatever agent or method used, ventilation should be adequate, oxygen concentration kept high, and hypercapnea prevented.

Frequently the first sign of worsening of a shocked patient's condition during anesthesia and surgery is the observation that decreasing quantities of anesthetic agents are required to keep the patient anesthetized. Failure of the anesthesiologist to realize this fact or to apprehend the sign will lead to a delay in the institution of treatment and the demise of the patient.

From the surgical viewpoint, it must be pointed out that speed is essential in performing operations upon patients in shock. Definitive surgery must be deferred until the patient's condition improves. The mortality rate associated with prolonged surgery in these situations will always remain high. The surgeon must be gentle with his manipulations. Roughness combined with the mandatory light plane of anesthesia may give rise to disastrous traction reflexes; disastrous in the sense that further hypotension or sudden cardiac arrest may occur, or in that it may become necessary to maintain a deeper plane of anesthesia to avoid reflex activity. For abdominal operations, minimal retraction should be employed, since that too may impede venous return to the heart.

Careful observation of patients in shock must be continued into the immediate postoperative period. As mentioned previously, movement of patients in shock or under anesthesia must be accomplished with caution and gentleness. Sudden turning or shifting of position can result in further hypo-

tension, deepening of shock, and death. Oxygen should be administered constantly. *l*-Norepinephrine may have to be administered continuously for hours or even days. Electrolyte studies must be made in order to detect and treat deficiency or excess of any particular ion. Narcotics and sedatives must be used sparingly. Usually, these patients are more restless from hypotension and relative hypoxia than from pain. Consequently, small doses of barbiturates may be more efficacious if sedation must be resorted to.

All patients who have received multiple transfusions must be watched carefully for continued bleeding at the end of the operative period or in the postoperative period. The cause for such oozing is not completely understood. This is discussed in detail elsewhere in this text. At present, the treatment normally employed for such excessive oozing is to administer freshly drawn blood or fresh frozen plasma.

Much investigative work concerning shock is in progress. The current thinking on the subject may well be outdated in a matter of months. Excellent symposia upon the subject have appeared and will continue to appear.

PRINCIPLES OF PREOPERATIVE AND POSTOPERATIVE CARE

Preoperative, Operative and Postoperative Care

By RICHARD L. VARCO, M.D.

RICHARD LYNN VARCO, born in Montana, was educated at the University of Minnesota, and has had teaching and research experience in the Departments of Medicine, Physiology and Surgery in his training for surgery. He is now Professor of Surgery. In their investigative work, he and his collaborators exemplify the rewards to the patient which can result from practical application of the principles of the basic sciences to the art of the practice of surgery.

INTRODUCTION

Medical students often freely concede that the numerous, at times intricate and perhaps tedious problems of preoperative and postoperative care fail to capture their interest quite as readily as do the more glamorous operative aspects of surgical practice. With experience, however, they are more willing to acknowledge that efforts devoted to these less dramatic activities are necessary to ensure a smooth or even successful convalescence. In fact, during recent years, the steady decline in the mortality and morbidity rates

for surgical procedures has depended in a fair measure on this wider recognition and practice of the principles of preoperative and postoperative care. Besides making any procedure safer, this knowledge has eased the restrictions against operating on both elderly persons and the very young. Now these patients need rarely be refused the most formidable type of operation solely because of age. Finally, through careful attention to these details, it has become possible to broaden, generously, without incurring an unreasonable hazard, the magnitude of sur-

gery undertaken to meet the most complex therapeutic problems.

PREOPERATIVE CARE

An orderly plan for the questioning and examining of each surgical patient, even in an emergency case, is of fundamental importance. In an emergency situation two major considerations deserve primary attention: First, the patient's ventilation should be adequate. The airway should be patulous and the chest wall and lung function acceptable for the maintenance of respiration. Ideally, problems related to this region are solved with the cooperation of an anesthesiologist equipped to insert an endotracheal tube, suction the air passages of any blood, mucus, gastrointestinal contents or foreign material and provide to the lungs a free flow of an oxygen-enriched mixture. As well, he can temporarily stabilize a flail chest wall and thereby overcome any respiratory paradox which had made voluntary respiration inefficient.

The second major consideration is the need for controlling persistent external bleeding. Internal hemorrhage of traumatic origin usually requires an operating room and the paraphernalia available there to insure its successful management. For visible blood loss, firm compression will usually stanch the flow, even when this is partly due to brisk arterial bleeding.

When adequate ventilation is established and means to maintain it, as well as control of external hemorrhage, blood should be secured for crossmatching and urine for analysis, the patient being catheterized if necessary.

Preoperative Routines. The student should learn to listen well in order to secure a maximum of information from the patient. To avoid the omission of pertinent details, many institutions provide outline guides for the history-taking and the physical examination. The student's methodical use of these forms is recommended until repetition and experience have stamped their essentials into his memory. Such discipline will contribute to the avoidance of grave and occasionally embarrassing oversights. A lengthy transcription of the history and a detailed description of the physical findings may try the student's patience until he realizes how that background becomes an important preamble to the intelligent care of each individual. After the patient's historical and physical data have been recorded, the following laboratory tests and roentgen-ray studies should regularly be obtained:

Analysis of the urine: specific gravity, albumin, sugar, acetone or diacetic acid and microscopic sediment.

Blood study: hemoglobin estimation and/or red blood cell count, total white blood cell and differential counts; measurements of the bleeding* and clotting times, typing of the patient's blood and prothrombin time, particularly when the history suggests the possibility of liver damage.

X-rays: Chest roentgenogram on 14-inch by 17-inch film. The surgeon should review all x-ray studies which he has ordered. Through such day-to-day comparison of the patient's clinical status with the salient features of the roentgenograms, he develops a keen ability to analyze even the more complicated problems.

A careful appraisal and correlation of the history, physical findings and laboratory data will serve as a guide to initiating care for the usual patient. In many surgical patients, it will represent an adequate preoperative work-up. Yet, the pathologicophysiological alterations of starvation, dehydration, anemia, diabetes and cardiovascular, renal, or pulmonary disease may be recognized in others. In some, the situation may prove to be so intricate that a variety of complex laboratory, roentgenographic and diagnostic procedures are required. Each patient's needs will have to be decided upon and these will sometimes require consultation to determine the best use of the more complicated and costly diagnostic tools. It is advantageous, whenever an excretory cholecystogram or urogram is likely to be included in the diagnostic work-up along with roentgen studies using barium as the contrast agent, to schedule the former first so as to avoid difficulty in interpretation by the residual blobs of opaque. For all laboratory tests forethought should be given as to their relevance, cost and urgency. Abuse of an emergency service by requests which are not genuine but rather are a substitute for reasonable anticipation will dull even the most cooperative technologist's ardor for service.

Nutrition. Oral preparation. The person who has been eating well and has lost little or no weight will require no special preoperative dietary management. On the con-

* During the menstrual phase in some women and frequently in patients with cyanotic congenital heart disease, markedly abnormal bleeding times are encountered. This need not preclude an emergency operation or a carefully evaluated elective one since with special attention to hemostasis the risk remains reasonable.

trary, the patient who has sustained a recent serious weight loss is malnourished, i.e., represents a substandard operative risk. Major operations performed on a group of these individuals will carry increased mortality and morbidity rates. This has been repeatedly demonstrated by many surgeons through sad personal experience. Therefore, surgical benefits are not infrequently denied the malnourished patient. If he is accepted without special nutritional rehabilitation after appraisal and acknowledgment of the increased hazards, the operative manipulations are often poorly tolerated. The patient may react unfavorably from the outset, with an instability of blood pressure out of proportion to the actual blood loss. Numerous transfusions at the time of operation seem to provide only transient support to the blood pressure. Convalescence is slower than normal and is disturbed by a greater incidence of complications such as ileus, impaired wound healing and disruptions, or stomal obstruction. This patient, already enervated by starvation, lacks the vitality to overcome such hazards and the surgical risks are greater than for a properly nourished subject.

Those bodily derangements produced by severe starvation are, hepatic dysfunction, impaired wound healing, hypoproteinemia and a contracted blood volume. These pathologic changes are reversible when appropriate dietary management is possible. The return to normal is slow and it requires many days or weeks of therapy to achieve recognizable nutritional restitution. Sudden and dramatic benefits are rarely obtained. The clinical problem is also complicated by a dearth of simple, accurate methods for precisely measuring the effects of starvation. Likewise, there is no test to indicate the quantity of nourishment required for the re-establishment of sufficient health to allow major surgery without excessive risk. Fortunately the restoration of the bodily economy to less than ideal performance suffices. After an adequate but partial nutritional restoration of the patient, the surgeon can operate and anticipate a convalescence as free from complications as in a standard-risk individual.

During periods of relative starvation, the patient becomes autocannibalistic. His energy requirements are derived principally from body protein or fat and he subsists on a low calorie, low protein, high fat diet. Logic suggests, and experience confirms, the characteristics of a diet most likely to cor-

rect the consequences of such starvation. In the laboratory and from clinical studies, it has been found that this diet should be rich in protein and carbohydrate, high in calories and low in fat content. Of all these constituents, protein plays a leading role. The principal sources of protein in natural foods are meat, fish, eggs, certain dairy products and cereals. Yet in each of these, the protein contributes but a small fraction of the total bulk. It becomes necessary, therefore, to give an enormous quantity of food when a large protein intake is desired. To achieve a protein intake of 300 gm. when beef is the source, about 1400 gm. of lean meat would have to be eaten. This gargantuan feat is usually beyond the capacity of a patient who is weakened and anorexic from prolonged starvation. However, reasonable quantities of tastily prepared and attractively served foods will foster the acceptance of a relatively high protein diet. Too, the stimulus of a freshly devised daily menu and the cooperative appeal from bedside consultations among the surgeon, dietitian and nursing staff will add vitality to this nutritional program. In analyzing the effectiveness of this regimen, reasonably accurate calculations of the caloric intake can only be made from reappraising those quantities which the patient does not eat. An erroneous judgment is almost certain if reliance is placed on equating a prescription for a high protein and caloric diet with its consumption. Certainly, every patient who willingly obtains the necessary quota from the available hospital fare should be encouraged to continue. Physical factors will, however, tend to limit the accomplishments possible by this means. In such cases, liquid feedings will provide a useful means of supplementing the protein intake. Milk is an excellent vehicle for such mixtures and will hold substantial quantities of protein concentrate and carbohydrate. A wide variety of protein concentrates or digests are available. Skimmed milk powder, about 33 per cent protein, is among these. It is inexpensive, is widely available, stores well in bulk form and can be disguised to enhance its palatability. Its proteins are complete and possess a better than average capacity to induce plasma protein regeneration.

The use of a liquid diet to supplement the hospital fare, or as the sole source of calories, is valuable and finds frequent application in patients with lesions of the esophagus, stomach and duodenum. When mild to severe degrees of obstruction complicate the pre-

operative status, a liquid diet is particularly beneficial. Not uncommonly, incomplete mastication of solid food results in even greater degrees of obstruction. When this occurs, one should lavage the chunks of swallowed food by means of a large-bore gastric tube (36 French) and thereafter a satisfactory amount of a liquid diet will pass the stenotic area each twenty-four hours. Several diets have been tried at the University of Minnesota Hospitals, but the following, with minor variations, has been the most adaptable:

*Liquid Diet (2416 Calories)**

	CARBO- HYDRATES (GM.)	PRO- TEIN (GM.)	FAT (GM.)
Whole eggs, 6		36.0	36.0
Egg whites, 2		8.0	
Skimmed milk powder, 4 oz.	58.8	40.4	1.2
Lactose, 300 gm. (beet or cane sugar may be substituted)	300.0		
Skimmed milk, 1000 cc.	50.0	36.0	
Salt, 5 gm			
	<u>408.8</u>	<u>120.4</u>	<u>37.2</u>

* About 1.6 calories per cc.

This mixture passes readily through a 16F nasogastric catheter or a small Penrose drain. Tubes constructed of plastic are less annoying to the patient than are those of other materials, particularly when they must lie in place for several days. This liquid diet can be dispensed through a drip-feeding apparatus. For this arrangement, the best functioning containers have been adapted from intravenous flasks with dependent air vents. This permits the entering bubbles, as they rise, to agitate the mixture gently, reducing the tendency toward sedimentation and plugging. A Murphy drip apparatus is inserted into the connecting tubing and the visible rate of flow can be regulated by the patient by means of a thumb screw attachment. Particularly in the case of a feeble person, it is a wise precaution to have the head of the bed elevated while the patient is being drip fed. Excessive sedation should be avoided for the same reason, i.e., to reduce the likelihood of overfilling the patient, which may result in regurgitation, aspiration and pneumonia.

For those who prefer to drink the above described mixture, the taste is similar to an eggnog. This flavor can be readily modified with chocolate, vanilla or other obvious choices. The diet can be used by outpatients also. Simple mimeographed directions about

its preparation, the volume to be consumed daily and the refrigeration requirements should be given to the outpatient, together with instructions covering the importance to the patient of drinking the prescribed amount. Whenever this liquid diet constitutes the sole source of food for the patient, he should be urged to take daily, if possible, about 5000 calories, i.e., 3 liters. When it is used as a supplement to ordinary fare, the consumption of 1 liter may suffice. Diarrhea will sporadically occur in persons receiving this diet, but it can largely be avoided by keeping unused portions of each freshly prepared batch under refrigeration and by the use of clean or sterilized dispensing equipment. If diarrhea occurs despite these precautions, small doses of paregoric and/or Amphojel will ordinarily correct the situation. Patients with regional enteritis or ulcerative colitis are rather consistent exceptions to this rule and should be tested with small amounts to determine their individual tolerance. For a hospitalized patient, the use of this liquid with a fixed caloric value per cubic centimeter simplifies the calculation of the daily caloric intake on the basis of the volume consumed. The amount is charted, preferably as calories, along with the temperature, pulse, respiratory rate, fluid intake, output volumes and body weight. The nutritional status is thus brought into focus at the bedside while rounds are being held. This close contact with dietary management through a day-to-day accounting of progress or loss is of fundamental importance for the consistently effective preoperative care of the substandard risk patients.

It is important when dietary preparation is required that it take place in the preoperative phase, because the weight of investigative evidence indicates a greater percentage of nitrogen retention than from protein ingested soon after operation. The establishment of any large nitrogen gain then offers considerable difficulty because of the catabolic phase present in the immediate postoperative period. The problem becomes even more awkward when the enteral route is no longer available, as is likely in this phase because of ileus or vomiting.

Objective measurements of the accomplishments of this hyperalimentation regimen are virtually nonexistent. Until more critical tests are available, the method to be presented offers a reasonably reliable means of calculating the duration of the special dietary regimen. First, it is important to find out the approximate amount of weight

trary, the patient who has sustained a recent serious weight loss is malnourished, i.e., represents a substandard operative risk. Major operations performed on a group of these individuals will carry increased mortality and morbidity rates. This has been repeatedly demonstrated by many surgeons through sad personal experience. Therefore, surgical benefits are not infrequently denied the malnourished patient. If he is accepted without special nutritional rehabilitation after appraisal and acknowledgment of the increased hazards, the operative manipulations are often poorly tolerated. The patient may react unfavorably from the outset, with an instability of blood pressure out of proportion to the actual blood loss. Numerous transfusions at the time of operation seem to provide only transient support to the blood pressure. Convalescence is slower than normal and is disturbed by a greater incidence of complications such as ileus, impaired wound healing and disruptions, or stomal obstruction. This patient, already enervated by starvation, lacks the vitality to overcome such hazards and the surgical risks are greater than for a properly nourished subject.

Those bodily derangements produced by severe starvation are hepatic dysfunction, impaired wound healing, hypoproteinemia and a contracted blood volume. These pathologic changes are reversible when appropriate dietary management is possible. The return to normal is slow and it requires many days or weeks of therapy to achieve recognizable nutritional restitution. Sudden and dramatic benefits are rarely obtained. The clinical problem is also complicated by a dearth of simple, accurate methods for precisely measuring the effects of starvation. Likewise, there is no test to indicate the quantity of nourishment required for the re-establishment of sufficient health to allow major surgery without excessive risk. Fortunately the restoration of the bodily economy to less than ideal performance suffices. After an adequate but partial nutritional restoration of the patient, the surgeon can operate and anticipate a convalescence as free from complications as in a standard-risk individual.

During periods of relative starvation, the patient becomes autocannibalistic. His energy requirements are derived principally from body protein or fat and he subsists on a low calorie, low protein, high fat diet. Logic suggests, and experience confirms, the characteristics of a diet most likely to cor-

rect the consequences of such starvation. In the laboratory and from clinical studies, it has been found that this diet should be rich in protein and carbohydrate, high in calories and low in fat content. Of all these constituents, protein plays a leading role. The principal sources of protein in natural foods are meat, fish, eggs, certain dairy products and cereals. Yet in each of these, the protein contributes but a small fraction of the total bulk. It becomes necessary, therefore, to give an enormous quantity of food when a large protein intake is desired. To achieve a protein intake of 300 gm when beef is the source, about 1400 gm. of lean meat would have to be eaten. This gargantuan feat is usually beyond the capacity of a patient who is weakened and anorexic from prolonged starvation. However, reasonable quantities of tastily prepared and attractively served foods will foster the acceptance of a relatively high protein diet. Too, the stimulus of a freshly devised daily menu and the cooperative appeal from bedside consultations among the surgeon, dietitian and nursing staff will add vitality to this nutritional program. In analyzing the effectiveness of this regimen, reasonably accurate calculations of the caloric intake can only be made from reappraising those quantities which the patient does not eat. An erroneous judgment is almost certain if reliance is placed on equating a prescription for a high protein and caloric diet with its consumption. Certainly, every patient who willingly obtains the necessary quota from the available hospital fare should be encouraged to continue. Physical factors will, however, tend to limit the accomplishments possible by this means. In such cases, liquid feedings will provide a useful means of supplementing the protein intake. Milk is an excellent vehicle for such mixtures and will hold substantial quantities of protein concentrate and carbohydrate. A wide variety of protein concentrates or digests are available. Skimmed milk powder, about 38 per cent protein, is among these. It is inexpensive, is widely available, stores well in bulk form and can be disguised to enhance its palatability. Its proteins are complete and possess a better than average capacity to induce plasma protein regeneration.

The use of a liquid diet to supplement the hospital fare, or as the sole source of calories, is valuable and finds frequent application in patients with lesions of the esophagus, stomach and duodenum. When mild to severe degrees of obstruction complicate the pre-

other plasma volume expanders dextran and PVP. The contribution of gelatin to parenteral nitrogen therapy is dubious.

Protein hydrolysate mixtures are obtained from the acid or enzymatic hydrolysis of a variety of substrates. The resultant commercial preparations, usually after tryptophan enrichment, are widely available. Casein has frequently furnished the source of protein in these digests. The hydrolysates are readily infused as 5 per cent solutions with an equal or lesser concentration of glucose. A rate of infusion of about 400 cc. per hour is well tolerated in most cases. If the injection is much faster, the incidence of unpleasant systemic reactions increases. The total nitrogen intake from parenteral use of hydrolysate mixtures is, therefore, limited to a smaller value than when the oral route is available. The total urinary nitrogen loss in twenty-four hours following venoclysis of hydrolysates and glucose is greater than after the feeding of equivalent amounts of skimmed milk powder. Despite these limitations of parenteral therapy, the hydrolysates occupy an important role in nitrogen replacement therapy. Through their agency, it is possible to retard the steady protein losses from starvation and allied depleting mechanisms such as ulceration, sepsis and hemorrhage. Testosterone, in the Depo form as cyclopentylpropionate, has some anabolic effect and, hence, could curb the nitrogen losses. Use of this hormone unfortunately induces sodium retention. Therefore, intake of this electrolyte should be restricted (75 mEq. per day), particularly in the case of the malnourished person.

The daily nitrogen intake is most substantially augmented by repeated transfusions of plasma or whole blood, a regimen which is not followed by a prompt "neutralizing" increase in the urinary nitrogen losses. Blood transfusions are preferable in the anemic patient, to be sure. Blood volume determinations, calculated for the usual weight prior to the current illness, provide a fair analysis of these requirements. Practically, this is a somewhat demanding technical procedure for routine care. Daily infusions of 500 to 1000 cc. of whole blood should continue until the hemoglobin and hematocrit values reach and remain in the normal range. And as a corollary, it can be expected that until the patient's normal blood volume has been reached, successive transfusions will not bring the hematocrit above a normal value. For the poorly nourished patient, as much as 2500 cc. of blood may be required. These

patients often suffer from a contracted blood volume and are poor operative risks until the blood volume is restored. A high grade correction of this hypovolemic-reduced red cell mass defect can be customarily realized by this plan. The associated hypoproteinaemia is less regularly and predictably restored to normal, because slight changes in these values are in "dynamic equilibrium" with quantitatively large debits in the total body protein. The plasma protein value can be raised additionally by the injection of albumin; however, it is costly, not always available, nor frequently necessary. After this phase of blood volume replenishment, a daily transfusion of plasma and/or whole blood, plus at least 3 liters of hydrolysate-glucose mixture, can be relied upon to provide the soundest possible parenteral preparation. At least a partial restoration of these various depots is essential in order to fulfill the aggressive protein demands of the healing tissues, the countless maturing phagocytes and the reticuloendothelial elements creating immune bodies in response to infectious processes.

This type of preparation represents a more complicated problem. It requires the services of a conscientious, tactful and patient house officer with sufficient skill to minimize the development of thromboses in all the cutaneous veins available to and essential for a prolonged period of intravenous therapy. In this connection, use of a forearm vessel away from the antecubital fossa avoids the distress of hyperextension at that joint. Also, it permits some latitude of movement without the danger of dislodging the needle and burying it into adjacent tissue, thereby causing a painful perivenous injection. In anticipation of a prolonged intravenous therapy program, sterile, small-bore polyethylene tubing can be inserted through the lumen of a large intravenous needle and into the blood stream. It may then be fastened with a dressing and left in place for several days. This conduit can be connected to the drip apparatus and avoids the need for frequent punctures of the patient's arm veins and frazzling of dispositions. At the conclusion of each day's infusion schedule, the tubing should be flushed with a few cubic centimeters of isotonic saline solution containing heparin and then plugged with a sterile intravenous needle of appropriate size to which has been attached a 2 cc. syringe containing a dilute solution of this anticoagulant. It then remains patulous and ready for the next injection. When there is

that the patient has recently lost. This figure should regularly be available and recorded in the admission history. Patients often do not know the exact amount of weight lost but nearly always are able to recall a maximum weight determined for some time during the previous three to six months and this can be compared with the admission figure. Any decrease is more significant if expressed as a percentage of the total body weight. When this value becomes 25 per cent or more, a period of at least two weeks of dietary preparation is desirable. Each day the patient should try to consume about 4500 to 5000 calories. If this total is obtained solely from consumption of a mixed diet, the proportions of protein, carbohydrate and fat should approximate those indicated in the liquid diet mixture. These estimates for the duration and amount of augmented caloric intake have been tested by trial and error for many patients having nutritional problems and probably are maximal rather than minimal. If the patient has had an adequate nutritional preoperative preparation, he can usually leave the hospital after the same postoperative period that a standard-risk patient requires. In addition, effective preoperative dietary management of substandard-risk patients will result in shorter hospitalization periods than will neglect of this consideration, performance of an early operation and the development of a complicated convalescence or a protracted interval requiring nutritional rehabilitation.

In some nutritional problem patients, the oral route is not available for protein and caloric replenishment because of alimentary tract obstruction. Ulcerative or neoplastic disease of the esophagus, stomach or duodenum is the most common cause. Ultimately, a surgical procedure of considerable magnitude may be required to correct the pathologic condition. Two alternative methods are available for nutritional preparation. A jejunostomy can be made and the feeding mixtures then dripped into the intestine at its level. In many of these subjects, diarrhea, difficult to manage, develops before the quantity of material fed daily reaches the required caloric intake. This diarrhea often fails to respond despite recourse to a wide variety of dietary formulas and certain of the patient's limited reserves are depleted in the volumes of liquid stool lost.

Parenteral preparation. The other alternative is the establishment of a comprehensive parenteral feeding program, which strives to attain a dual goal: (1) to meet the

daily caloric requirements, (2) to acquire the maximum possible nitrogen retention. The caloric needs are supplied by glucose* in 5 to 20 per cent solutions. At least 200 to 250 gm. of carbohydrate daily is required to provide the body's energy needs. Unless this, or fat, is available, substantial quantities of either body protein or of infused nitrogenous material will continue to be catabolized for fuel. The degree of completeness of provision for this protein-sparing action by carbohydrate is, therefore, an essential component of the ebb and flow of nitrogen reservoirs. Solutions for intravenous use containing fat emulsions will provide energy units which thus reduce the drain on exogenous and endogenous protein as a source of calories. Their best feature is the high (9) caloric value per gram of fat. Limiting factors in their use are instability problems under varied climatic conditions and toxic systemic reactions, i.e., fever, chills, nausea, vomiting and headaches. In addition, our knowledge to date is incomplete concerning the late consequences of prolonged use of these infusions. Instances of hepatomegaly, a hemorrhagic tendency and lowering of the plasma albumin fraction have been reported. The frequency of these side effects appears roughly proportional to the number of bottles of intravenous fat given to the patient. Therefore, prevailing opinion favors the tendency to limit this amount to ten to twelve separate half-liter infusions. Meanwhile, its use for a specific need which cannot otherwise be met has considerable justification and reasonable safety, it may yield some temporary benefits in the nutritional care of severely burned patients requiring high caloric intakes.

The other major control of the state of the nitrogen balance comes through the kind and the amount of the nitrogenous compounds administered parenterally. The nitrogen-containing compounds available for parenteral use are pure amino acid mixtures, gelatin, protein hydrolysates, albumin, plasma and whole blood.

Pure amino acid mixtures are still rather costly and the limited supplies are largely

to the emergency in shock therapy if plasma and whole blood are not immediately available, as have also those

* If fructose is substituted, less will be lost in the urine even when the higher concentrations are administered, but the cost of the product is greater

rate volumetric replacement of the measured blood lost during the operation. This is particularly important because the prevention of shock is much more successful than its treatment. Too, the duration of the hypotension and the mechanism producing it are critical considerations in arriving at the prognosis for any specific case. Certainly, the longer the period with a profoundly low blood pressure (< 60 mm. Hg), which can be due to endotoxin shock associated with gram-negative bacteria in the blood, the poorer the outlook. This is in contrast to the situation in a patient suffering from brief hypotension due to acute hypovolemia which promptly responds to adequate transfusion.

The injudicious employment of sodium-containing parenteral fluids is capable of imposing a serious cardiac overload. Unless careful attention is focused on this issue, heart failure will develop in many patients with a low cardiac reserve. This sodium-retained accumulation of fluid can delay the operation or, remaining unrecognized and untreated, be fatal. As a corollary of this, abrupt restoration of low sodium values to "normal" levels may also have lethal consequences in a patient previously maintained on a low sodium diet for the control of his heart disease.

Pulmonary Disease. The presence of any substantial amount of pulmonary disease is ordinarily ascertainable from the history, physical examination and admission chest film, with an assist at times from electrocardiographic findings of *cor pulmonale*. Routine preoperative measurement of the vital capacity is desirable before every major operation. Any serious reduction is particularly important if the patient is asthmatic, emphysematous or has advanced pulmonary hypertension. The use of the one-second vital capacity test is an even more valuable index of functional capacity in these crippled people. The capacity should be at least 80 per cent of the total expiratory volume. A simple but functionally useful test of the patient's respiratory reserve is to walk up a few flights of stairs with him and note his tolerance to this amount of physical activity, that is, whether he is able to converse naturally without labored breathing.

Patients with excessive tracheobronchial secretions benefit from preoperative postural drainage of the respiratory tract, the use of surface tension-lowering and smooth muscle-relaxing drugs added to inhalants, avoidance of a very low environmental humidity, and

differential ventilatory instructions if a pulmonary resection is contemplated. Patients with frankly purulent sputum should receive appropriate antibiotic therapy based on Gram stains, cultures and sensitivity tests for the predominant organism. Until this condition has been cleared up, the patient is not a candidate for an elective operation. The prophylactic use of penicillin for several days preoperatively in such patients, as well as in those with related disorders, is an inexpensive precaution and appears to lower the incidence of postoperative pulmonary complications from atelectasis and pneumonia. Tobacco smokers, especially those addicted to the heavy consumption of cigarettes, should interrupt this habit for at least ten to fourteen days prior to an elective major procedure. Those patients awaiting a hernia repair, an extensive pulmonary resection or an abdominal operation likely to require a long midline incision are particularly benefited by the consequences of this action. Smokers are more likely to develop respiratory complications in the postoperative period than are nonsmokers. Even temporary preoperative discontinuance of this habit has an apparently beneficial effect.

Vitamins. The chronically malnourished patient may have either occult or manifest hypovitaminosis. If the clinical picture or laboratory tests suggest the diagnosis, specific vitamin therapy is indicated and, whenever the oral route is available, it is preferable. Intravenous preparations are more costly and their use should be reserved for those patients in whom the enteral route is unavailable because of obstruction, vomiting or diarrhea. In the absence of a deficiency requiring specific therapy, only vitamins B_1 , C and K are important in the routine surgical care of patients.

Thiamine (vitamin B_1) participates in those enzyme systems which regulate carbohydrate metabolism and maintain normal gastrointestinal activity. In any nutritional preparation involving large quantities of carbohydrate, liberal amounts of thiamine (10 to 20 mg. daily) are advised. Intravenous infusions of glucose rapidly deplete the existing stores of vitamin B_1 , thus aggravating any latent deficiency. Carbohydrate metabolism itself is impaired, further hampering the nutritional rehabilitation. Sulfasuxidine given orally will increase the thiamine requirements in the diet. When excess quantities of thiamine have been provided, they are either lost in the urine or stored and appear to cause no deleterious effects. The

a paucity of superficial veins, this method will help resolve that dilemma also. Caution is offered against routine use of the saphenous venous system lest one thereby provoke a high incidence of thrombophlebitis and phlebothrombosis. The saphenous vein is especially prone to those complications when it has been used for prolonged intra-venous therapy.

The preparation of this group of patients by parenteral feeding should be compressed into as short a period as possible. This applies even to those with marked weight loss, anemia, hypoproteinemia, edema and other stigmata of starvation. They are prone also to those complications unique to an inlying nasal tube, i.e., regurgitation and aspiration, and, while accepting parenteral alimentation, more liable as well, to the effects of prolonged postural immobilization. Usually, from seven to ten days can safely be devoted to achieving maximum nutritional benefits for them. Even less time may need to be spent in rehabilitating those patients who are only moderately malnourished from this same type of partial, high-alimentary tract obstruction.

The Obese Patient. The very obese patient requiring an elective operation also presents a substantial nutritional problem. To accept this patient for a major surgical procedure without due preparation is to accept an increased incidence of pulmonary-cardiovascular problems and wound complications. In other words, the technical difficulties during the course of the operation are enhanced and perhaps even beyond one's remedy. The excessively fat person should be earnestly advised to lose weight beforehand. Then he should be given a diet to follow and his adherence to it must be closely supervised by the doctor. If he is to undergo the safest operation, his wholehearted participation will have to be enlisted by reasoning with him and by pointing out the life-endangering consequences of rashly disregarding advice to lose weight. Any balanced, weight-reduction diet that is adhered to by the patient is satisfactory because the most important factors are a suitable protein and vitamin intake and patient cooperation. For this purpose, a simple yet effective plan allows the patient about 2 quarts of skimmed milk per day along with medical supplements to meet adequately the vitamin requirements. Obese adults will lose weight on this regimen. When the amount desired has been lost, based on standard weight and height tables, the individual becomes a far better surgical risk.

Anemia and Hypoproteinemia. Chronically ill patients regularly exhibit some degree of anemia and protein depletion. The total extent of these defects is masked to a greater or lesser degree by contractions of the blood volume and/or plasma volume, and protein reservoirs. As a consequence of this decrease in the red cell mass and in the total amount of circulating plasma protein, these patients are intolerant of additional blood loss during operation and display evidence of impaired wound healing and decreased resistance to infection. The term "chronic shock" has been applied in such cases.

Heart Disease. The patient with heart disease may require a major operation as urgently as does his healthier contemporary. With careful attention to certain details, his chances of successfully undergoing an abdominal or thoracic operation of magnitude can be greatly improved. An individual with historical or physical evidence of heart disease deserves to have any necessary additional studies carried out. Electrocardiography, cardiac fluoroscopy, venous pressure determination and a functional test of exercise capacity will furnish worth-while preoperative data. Whether the findings are nearly normal or grossly altered, they represent significant base lines for comparison with later values. In the event of a complicated convalescence, a suspicion of incipient trouble gains greater credence and is easier to verify with such information available. When frank heart failure is detectable on the basis of pulmonary congestion or effusion or by hepatomegaly, ascites of peripheral edema, then preoperative medical advice and management are advisable. Meanwhile, it is best to initiate a program of salt restriction, combined with the use of diuretics, unless contraindicated by serum electrolyte or renal factors.

Hypoxia, hypercapnea, shock, overhydration with an excessive salt intake and hyperkalemia are the most common surgically induced mechanisms functioning as potential or real precipitants of cardiac disaster. The avoidance of certain of these states is customarily the responsibility of the anesthesiologist and the most knowing and effective of these specialists will cooperate as a coequal member of the surgical team.

Shock can readily precipitate a cardiac crisis in an organ which is already diseased. When the surgeon has been warned by the admission history, the physical examination and special tests, he should take certain precautions. Among these is provision for accu-

requires time. Therefore, this program should be carried out in elective surgical cases on two or three occasions prior to the day of the operation. A final cleansing of the area adjacent to the incision is recommended just prior to application of the skin antiseptic in the operating room. In theory, the patient should not be shaved the day or evening before an operation because any scratches or abrasions of the skin created by this can become infected. If the operative incision then crosses such an area, these multiplying bacteria will be seeded into the depths.

Gastrointestinal Preparation. Insertion of a nine-holed gastric tube, and the application of continuous, gentle suction to it, the evening before any major intra-abdominal operation permits the surgeon to work with a collapsed bowel and facilitates any procedure thereon. This is especially effective in combination with a thorough cleansing bowel preparation in a patient requiring repair for a pendulous ventral hernia.

For operations upon the stomach and esophagus in the presence of obstruction, extra care should be taken to remove food debris, which can be a rich medium for pathogenic bacteria, particularly in an achlorhydric environment. Repeated washings with a large-bore tube are required upon these occasions to remove this partially digested material. This precaution effectively decreases the potential for regurgitation and aspiration of material which upon reaching the bronchioles and air sacs obstructs and necrotizes these tissues. Such a complication, assisted by any bacteria present, produces diffuse, even life-endangering, pneumonitis. The use of neomycin orally will effectively reduce the colony strength of the gastric bacterial flora.

In patients having incomplete or potential obstruction of the colon, it is highly desirable to prevent this from becoming complete. Otherwise, a preliminary decompression operation may be necessary in addition to the resection procedure later. Therefore, care should be taken not to force any substantial amount of barium proximal to a narrowed area in a patient in whom an x-ray examination seems necessary to confirm the nature of the large bowel obstruction.

The diet should be selected for its low residual content. The bulk and consistency of the stool can be effectively reduced also by giving Sulfathalidine, or Sulfasuxidine and neomycin by mouth. Mineral oil orally

several times daily will counteract a tendency to impaction above the lesion. If these measures prove ineffectual and some degree of obstruction persists, though it is still incomplete, the temporary use of continuous gastric suction may still obviate the necessity of colostomy. Any final nutritional preparation can then be accomplished through parenteral alimentation.

For any major abdominal procedure administration of 2 to 3 ounces of mineral oil by mouth the night before an operation, and when the nasal tube is removed, will minimize the distress of passing the first postoperative, often inspissated, stool.

Final Preparatory Steps. When an operation is likely to be started late, it is wise to begin to meet the patient's fluid requirements earlier in the day with an intravenous injection of 1000 to 1500 cc. of a 5 to 10 per cent glucose solution containing 6 to 9 gm. of sodium chloride together with any vitamin supplements. In addition to fulfilling some of the body's energy requirements, any tendency to preoperative dehydration is controlled. It is to be noted here that unless the patient voids or is catheterized before going to the operating room, serious vesical overdistention will develop before the patient can micturate or be catheterized postoperatively.

The availability of prepared preoperative order sheets on the surgical stations simpli-

Preoperative Order Sheet

1. Scrub _____
1. Entire patient with G-11 soap _____ area
2. Fluids today _____
- _____ cc 5% glucose in distilled water
- _____ cc 5% glucose in saline
- _____ cc 10% glucose in distilled water
- _____ cc _____ and with _____
- 3 Tap water enema _____ tonight
- _____ A.M.
- 4 Draw blood and crossmatch _____ bottles
5. Pentobarbital, mg _____ h.s.
- _____ A.M.
- 6 Weigh patient before going to O.R. in A.M.
7. Nothing by mouth after _____ A.M.
- _____ P.M.
- 8 Insert nine-holed nasogastric tube _____ P.M.
- (Connect and check function of it)
- 9 Insert (connect and check function of it) urinary catheter _____ P.M.
- (Have patient void before being taken to O.R. if not catheterized) _____ A.M.
- 10 Wrap both limbs (toes to groin) with elastic bandages _____ A.M.
- _____ P.M.
11. On call from O.R. morphine sulfate _____ mg.
- atropine _____ mg.
- codeine sulfate _____ mg.
- Demerol _____ mg.

preferred route for administration is the oral one, because of the slower absorption and hence more prolonged systemic action. If thiamine is given intravenously with glucose solutions, the daily dosage should be divided, lest an unnecessary excess of the vitamin be lost by diuresis.

The contribution of *vitamin C* to wound healing is clearly established. A low tissue *vitamin C* content is correlated with an increased incidence of wound disruption, the edges of which would reveal a collagen-formation deficit. The plasma ascorbic acid content can be readily measured. *Vitamin C* deficiencies result from an inadequate intake, faulty intestinal absorption or an excess loss from, or sequestration by, the tissues. In the instance of burns, abscesses or large ulcerating areas, this mechanism can increase the daily requirements to at least 1000 mg. Tissue saturation is easily attained by means of oral preparations and parenteral solutions are available when that route cannot be used. Yet no large-scale, long-term storage probably exists in man. Any superfluous intake is lost in the urine, causing no harmful reaction. A daily dose of 500 mg. is ample for most contingencies met with in the preparation of surgical patients.

A prolonged deficiency of *vitamin K*, a fat-soluble vitamin, disrupts the clotting mechanism by preventing the formation of prothrombin by the liver. The resultant

stage K deficiency is any mechanism which prevents its formation in, and absorption from, the intestinal tract. Prolonged oral use of poorly absorbed antibiotics can so reduce the bacterial flora of the intestine as to inhibit *vitamin K* synthesis sufficiently to cause serious hypoprothrombinemia. In some types of biliary obstruction, or with an external biliary fistula, the emulsifying action of bile is lost and consequently this naturally fat-soluble *vitamin* cannot be absorbed. *Vitamin K* should be given parenterally in such cases. Hypoprothrombinemia occurs also in association with severe hepatic disease and if the plasma prothrombin value is not correctable to around 80 per cent of the normal with therapeutic amounts of parenteral *vitamin K*, it becomes of grave prognostic significance.

Essential hypoprothrombinemia, a rare disease and conceivably a congenital metabolic defect, is an exception since other evidence of hepatic disease may be lacking in

these patients. For those persons with hypoprothrombinemia which is not benefited by *vitamin K* therapy, massive transfusions of freshly drawn plasma or whole blood will temporarily elevate the plasma prothrombin content and the bleeding tendency can usually be controlled sufficiently to permit an operation. In any emergency, minor defects of circulating prothrombin concentration can be so managed. With the availability of *vitamin K₁* oxide for intravenous use, a more prompt restoration of prothrombin content to circulating blood is now possible even in persons who have been receiving Dicumarol-like compounds.

All patients suspected of being hypoprothrombinemic should have a test for prothrombin concentration. This result is usually checked by determining the plasma prothrombin time of a normal patient's plasma, used as a control for the materials and methods. Also, this function can be charted as the percentage of normal prothrombin activity: the normal patient's plasma prothrombin time divided by the patient's plasma prothrombin time multiplied by 100. The prothrombin percentage can be calculated from a curve derived by plotting prothrombin times against serial dilutions of normal plasma. The curve is accurate as a standard only when the same potency of thromboplastin used in obtaining the curve is used for testing the unknowns. Prolonged bleeding is unlikely to occur unless the patient's prothrombin time is more than twice that of the control, or until the percentage of activity is lower than 50 per cent. In most instances of *vitamin K* deficiency, considerable response is seen within twenty-four to thirty-six hours after therapy is started. A daily dose of 5 to 10 mg. of *vitamin K* customarily will suffice for this purpose. Quantities of the *vitamin* in excess are well tolerated and apparently do no harm. Water-soluble preparations for parenteral use are available whenever medication cannot be given orally.

Skin Preparation. The currently vexing difficulty with wound infections, unfortunately often of staphylococcal origin, stems from multiple sources. One of these is from organisms within the patient's own dermal crypts. Some protection against this locus can be realized by repeated lathering of the patient's entire body with soapsuds containing hexachlorophene. For the ambulatory individual, this need be no more than particularly thorough sessions in the shower. The action of this surface-acting germicide

Hypoxia and Hypercarbia. Avoidance of hypoxia is largely in the province of the anesthesiologist. It is his obligation to insure an open airway at all times, from the moment of induction through the recovery of consciousness. Having developed a patent airway, his next commitment is to provide for adequate pulmonary ventilation with an oxygen-rich mixture. Whenever the patient fails to, or cannot, respire deeply enough, the prevention of hypoxia is incumbent on the anesthesiologist.

Far more insidious than hypoxia, and at least as detrimental to the patient's welfare, is hypercapnea. The gradual accumulation of significant volumes of carbon dioxide in the anesthetized patient's blood, due to inadequate ventilation, produces profound metabolic consequences when allowed to persist for any substantial time. This treacherous situation has few overt manifestations likely to alert the anesthesiologist. Direct measurements of p_{Ht} on the circulating arterial blood or analyses of the expired breath are revealing of the problem's magnitude. Other than in those institutions actively studying some aspect of ventilatory problems, however, the carbon dioxide analyzer is not routinely used by anesthesiologists, despite the fact that this instrument is readily available, clinically important and has an acceptable accuracy over a reasonable clinical range. In the absence of such precautionary devices, the only protection against hypercarbia is an unflinching attention to the maintenance of effective manual or mechanical ventilation. A failure to recognize the pile-up of carbon dioxide, until the accumulation is able to produce severe acidosis, may well be an initiating factor capable of triggering abnormal vagal reflexes and cardiac standstill. Moreover, hypercarbia through its vasopressor effect may mask coexisting hypovolemia and the latter becomes disastrously apparent only when the blood carbon dioxide tension has been reduced toward normal.

POSTOPERATIVE CARE

The unconscious or semicomatose patient should be returned from the operating room with the head lower than the feet on a cart designed to be elevated at one end. As a substitute procedure, he can be positioned flat on his side with the dependent thigh and knee flexed and the upper one extended to provide some rotational stability. The head then lolls from the shoulder, allowing secretions to drain away. Whatever the posi-

tion or method of transport, a clear airway is the first consideration and a periodic check should be made even while the patient is en route from the operating room to his bed. The principal object of either the head-down or alternative position is to prevent regurgitation and aspiration. Certainly, saliva or gastrointestinal contents which are allowed to accumulate in the tracheobronchial tree postoperatively are a major cause of atelectasis, pneumonitis and pneumonia. An effective prophylaxis against this occurrence is the routine use of gastric siphonage during an operation. This arrangement will also minimize the development of distention secondary to the anesthetist's pumping of gas into the intestinal tract while he is forcefully ventilating the patient by means of a face mask. In the early postoperative phase, repeated nasopharyngeal aspirations are frequently required to care for the gathering saliva when the volume exceeds the patient's capacity to handle it.

The use of a recovery ward in proximity to the operating room represents a current trend which has already earned approval at many institutions. When this very helpful arrangement exists, all anesthetized patients should be kept there during the immediate postoperative phase, until vital signs are stable and the individual responds to inquiry. This grouping is conducive to the establishment of more efficient routines. Likewise, the management of postoperative emergencies will be improved since responsibility for the patient's nursing care during the important first few hours is met by this trained organization. Too, changes in, and education of, this numerically more limited personnel are less troublesome than when the entire nursing surgical service must be exposed to the many individual variations occurring in the postanesthesia recovery period. In turn, any newcomer to the recovery room rapidly gains concentrated experience in the recognition of most types of early postanesthetic and surgical difficulties. Intelligent and alert bedside nursing by someone well oriented in such problems is essential to the routine achievement of smooth convalescence.

Oxygen therapy equipment, tracheostomy trays, transfusion apparatus, motor-driven suction and other resuscitative equipment and drugs should be kept on hand for prompt use. A well trained group of nurses and doctors staffing a recovery ward can demonstrate teamwork in the management of an with cardiac arrest. This

fies this stage of readying the patient for his operation. It also serves as a useful check list of the customary things to be done

Discussion of the Operation with Patient and Relatives. The preoperative preparation

procedure contemplated. A discussion of the operation should include clear-cut explanations as to why it is necessary. It is particularly important to describe the consequences to a person about to undergo colostomy, an amputation, a visibly deforming procedure, an endocrine removal certain to require substitution therapy or to alter the patient's life-giving powers. This discourse must be carefully balanced so as to be informative but not anxiety inducing and is always to be couched in terms of interest in the person and with sympathy for his problem.

Upon completion of an operation and after ascertaining that the patient is doing satisfactorily in the immediate postanesthetic phase, the thoughtful surgeon communicates with the relatives. He should devote as much time as may be required to a forthright discussion of the problems encountered and how they are being solved, and he should appraise the likelihood for a successful outcome. This can be reassuring to those in waiting who are naturally anxious.

OPERATIVE CARE

During an operation, attention should continue to be focused on the same physiologic factors which were of concern preoperatively, i.e., any blood, electrolyte or fluid deficiencies, together with attention to cardiorenal and pulmonary dysfunction. The employment of a scale for accurately weighing the blood lost during the operation is of value. Throughout the dissection dry fluffs and packs are used to collect blood and, in addition, all blood suctioned from the field is collected into a calibrated trap system. Inasmuch as the tabulation is kept current by an attendant, a running account of the blood loss is available to the surgeon. The resultant figure is uniformly on the low side of the actual volume of blood lost and should be so interpreted when the amount of blood for transfusion is being decided.

Exposed viscera should be protected against dehydration by covering them with packs moistened in saline or Ringer's solution. Otherwise, various types and sizes of dry sponges are employed and when they become blood stained and have been passed

out of the sterile field to be counted by a circulating nurse, their gain in weight can be tabulated. This gravimetric determination of the blood loss compares reliably with either colorimetric or isotopic estimates. The wisdom of shock prevention versus shock therapy is endorsed by providing the patient with an amount slightly in excess of those volumes which have been measured. Furthermore, a surgeon who is regularly confronted with objectively calculated blood losses larger, for comparable procedures, than those his colleagues find necessary, can profitably speculate about his record and his methods for hemostasis.

For children up to 20 kg. in weight, use of a scale in the operating room is also a highly accurate means of measuring the total blood loss during an operation. If the child has been precisely balanced just before the operation begins, the only change at the termination of the surgical procedure must be from blood loss and the specimen removed.

The fluid losses through sweating during a prolonged operation can be considerable in an adult if the weather is hot and the operating room is not air conditioned. These fluid requirements should be met by replacement of water and electrolytes during the operation. Maintenance of adequate hydration will reduce the number of mechanisms provoking postoperative oliguria. The routine inclusion of a well functioning intravenous set-up among the operating room facilities is, therefore, strongly recommended for all major procedures. This equipment should be so adaptable as to permit the ready infusion of a variety of solutions and should include a cannula, or needle, suitable for rapid transfusions. Either the antecubital or the saphenous vein may be used, but the needle must be shielded from possible dislodgment during operative manipulations.

For surgical procedures of any duration, some protection should be provided for all the patient's bony prominences. A sponge rubber or air mattress is best, but air-filled rings will suffice. A scrawny individual, in particular, can readily acquire areas of pressure necrosis unless protected. The unrelieved weight of the patient, the drapes,

elbow to prevent pressure palsy of the ulnar nerve is always a wise precaution.

should be avoided. With this sac about the heart widely cut and one hand placed inside, effective cardiac massage can be instituted. The rate (80 to 100 per minute) of manual compression is important and should be adequate to provide a detectable pulse at the wrist or over the carotid artery. Increased cardiac filling is usually obtainable by placing the patient in a limited Trendelenburg position. In those instances of cardiac arrest when, after a few minutes of vigorous massage and with restoration of a pinker hue to the myocardium, the heart fails to recapture effective tone despite a regular rhythm, then an intraventricular injection of epinephrine (0.5 cc. of 1:1000) may prove effective. Once an airway adequate for effective ventilation has been achieved, and after the establishment of a modest circulatory pressure by efficient cardiac kneading, then the next steps designed to retrieve this situation can be managed in a more leisurely fashion. The need for planned, coordinated, prompt action to achieve these two primary objectives is to be emphasized, however. That state can only come about when considerable forethought has been given to the management of this recurring problem by those individuals responsible in any post-anesthesia recovery room and on the surgical service. Opportunities for practicing such steps on the medical wards are in existence, but they are even less likely to be carried out successfully because of an over-all unfamiliarity with procedural details and lack of essential equipment.

Ventricular fibrillation may be the initial presenting complex when the pericardium is opened. If so, no great haste is indicated to convert this vermiform, inefficient activity to a normal thrust. A more important objective during those crucial first minutes is to restore, by manual massage, an effective blood flow while the patient is simultaneously being well ventilated. Moreover, in certain instances of fibrillation handled by massage, once adequate ventilation has been achieved, spontaneous reversion to a normal rhythm occurs. On the other hand, efforts to defibrillate a cyanotic, dilated heart will usually prove to have been in vain and more brain damage will result. Cardiac tone must be restored and the myocardium be well oxygenated if defibrillation is to succeed. Defibrillation requires the use of an instrument capable of delivering, ideally for brief periods (0.1 to 0.5 second), 110 to 250 volts of low amperage current which is then distributed broadly on the heart surface by

paddle-shaped electrodes applied firmly to opposite sides of it. In the better-made instruments, it is possible to set rather precisely the duration of this electrical pulse, thereby minimizing the total amount of heat delivered to the already damaged heart. Since lower voltage levels might prove incapable of converting the heart to a regular rhythm, it is necessary that the instrument at hand be capable of discharging up to 250 volts. In order to prevent electric shock to the individual manipulating the handles of this defibrillating instrument, it is vital that he be insulated with rubber gloves free of any holes and that there be no other contact with the patient. Use of an isolation transformer prevents grounding through the operator and limits the dangerous contact to a single electrode. Compact defibrillation units are now commercially available and should be looked upon as essential equipment in modern hospital operating rooms or postanesthesia recovery areas. Adequate units should be handily available to the surgical convalescent floors.

Intracardiac injection of M/7 sodium lactate, or a solution of 7 percent sodium bicarbonate, in 10 to 50 cc. increments will facilitate subsequent electrical defibrillation of a heart recalcitrant to the establishment of a normal rhythm despite massage and previous electroshocks. It should be recalled in this regard that until the tissue pH has been restored to normal values from the state of metabolic acidosis present in hypoxia, the pharmacologic effectiveness of pressor amines is materially reduced. After correction of the pH, the heart, if still flabby in tone, will derive appreciable benefit from the judicious use of dilute solutions of epinephrine (0.5 to 1.0 cc. of 1:10,000) introduced into the blood perfusing the myocardium.

When adequate additional assistance becomes available at any stage of this rapidly moving sequence of events, someone should be delegated the responsibility of placing a wide-bore cannula of metal or polythene into an acceptable peripheral vein. The availability of this route for infusion is always helpful and may prove of considerable importance at any given moment. The ability to establish deftly a cut-down type venous cannulation, leading to a smooth-working infusion, is a modest skill, yet one to be admired and cherished by the surgeon regardless of his stage of development.

Continued observation of the cardiac behavior is indicated for at least a half-hour

is as emergent a situation as can confront any doctor and must be handled promptly, decisively and effectively in order to provide that patient with the best opportunity for survival despite this catastrophe.

Cardiac Arrest and Resuscitative Measures. The term "cardiac arrest" is meant to include all forms of cardiac standstill in asystole or ventricular fibrillation wherein the heart is no longer able to propel a sufficient volume of blood through the circulatory system to produce a detectable blood pressure. With either cardiac standstill or the ineffectual motions of ventricular fibrillation no more than a few minutes must be allowed to intervene before the circulation is restored, if death or irreparable brain damage is to be prevented. The cells of the cerebrum are particularly vulnerable to the metabolic consequences of circulatory stagnation associated with cardiac arrest. After an interval of no more than five minutes, their destruction progresses rapidly and so, even though other major organ systems may ultimately be restored, including effective cardiac activity, the individual may have been made decerebrate during this period of inadequate cerebral blood flow. The suggestion to reduce the self-destructive metabolic demands of the brain by prompt utilization of general hypothermia (30° to 32° C.) has much to recommend it, once an effective cardiac beat has been restored. Any tendency to shivering or convulsions must then be eliminated with muscle-paralyzing drugs to avoid inducing thereby an increase in body temperature. It may be necessary to maintain the lowered body temperature for twenty-four to seventy-two hours before restoration to a euthermic state is safe.

There are many methods of preventing this grave complication, but it is to be emphasized that a definite number of such instances can clearly be identified as arising from improper anesthetic techniques, with particular reference to the management of high levels of carbon dioxide accumulation in the blood during the anesthetic interval. Hyperventilation, even with air, under these circumstances can trigger a bout of ventricular fibrillation.

It is crucial to the success of these resuscitative measures that provisions be made in advance for handling this situation, firstly, that the equipment required be available and, secondly, that the principles involved in surgical technique be clearly understood. An airway must be promptly established and adequate ventilation achieved. A tank, valve

and conduction system capable of delivering oxygen in high concentration to a tight-fitting mask, or even better into an endotracheal tube, is quite acceptable. When this equipment is unavailable, then mouth-to-mouth insufflation should be tried. Any arrangement selected must permit satisfactory ventilation of the lung after this organ collapses following the opening of the chest. A prolonged search for mask, oxygen tank, surgical instruments and related paraphernalia converts an outlook grim, at best, into a hopeless cause.

All but those experienced in handling this complication will have major qualms about opening the chest when suddenly faced with that need in a patient presumed to have developed "cardiac arrest." At this moment of decision, there can be no justification for debate or procrastination while seeking a superior to accept this grave responsibility. The need must often be met by an intern or young house officer. An indecisive attitude will inevitably prejudice the outcome or even preclude any hope for success. Even an unduly long interval, while the doctor is seeking conscientiously with his stethoscope to be sure of a distant heart beat, may jeopardize the patient's slim chance. Unless one would forfeit the patient's life by further hesitancy, this diagnosis must either be confirmed promptly or disproved. The best method of resolving one's misgivings is to make a limited incision over the region of the fifth intercostal space. If this cut fails to bleed in the usual vigorous fashion that any wound should, then the operator can proceed with reassurance that that patient does, indeed, have cardiac arrest. In addition to decreasing the interval left to conjecture or speculation, there are therapeutic advantages of settling this quandary. Additional moments may unfortunately be lost in a search for sterile instruments and skin antiseptics. While certainly desirable, such preparations may not be available and their lack is not likely to be critical. Thanks to man's native resistance and the protection provided by antibiotics, one can rely on the use of a clean, but not aseptic, technique. This compromise will usually prove a wiser choice than blind insistence on rigid Listerian principles. When, during the course of subsequent steps, it becomes feasible to shift to sterile instruments and equipment, this should surely be done.

Once the chest has been opened and the heart exposed, the overlying pericardium should be incised, but the phrenic nerve

should be avoided. With this sac about the heart widely cut and one hand placed inside, effective cardiac massage can be instituted. The rate (80 to 100 per minute) of manual compression is important and should be adequate to provide a detectable pulse at the wrist or over the carotid artery. Increased cardiac filling is usually obtainable by placing the patient in a limited Trendelenburg position. In those instances of cardiac arrest when, after a few minutes of vigorous massage and with restoration of a pinker hue to the myocardium, the heart fails to recapture effective tone despite a regular rhythm, then an intraventricular injection of epinephrine (0.5 cc. of 1:1000) may prove effective. Once an airway adequate for effective ventilation has been achieved, and after the establishment of a modest circulatory pressure by efficient cardiac kneading, then have this situation

coordinated,

prompt action to achieve these two primary objectives is to be emphasized, however. When adequate additional assistance becomes available at any stage of this rapidly moving sequence of events, someone should be delegated the responsibility of placing a

polythene into in. The avail-

...usion is always helpful and may prove of considerable importance at any given moment. The ability to establish deftly a cut-down type venous cannulation, leading to a smooth-working infusion, is a modest skill, yet one to be admired and cherished by the surgeon regardless of his stage of development.

Continued observation of the cardiac behavior is indicated for at least a half-hour

after its condition has improved and while the general situation is being tidied up. This interval can be spent in acquiring sterile instruments and drapes to replace any unsterile equipment used in the emergency. If, after this interlude, the systemic pressure is reasonably normal, assuring a respectable coronary flow, the pericardium should be closed loosely, with one or two sutures, in order to prevent prolapse of the heart into the pleural space. Tubes should be introduced into the thorax which will provide effective drainage for any postoperative intrapleural accumulations of plasma and blood. Any incidental air leak occasioned by a rapidly executed thoracotomy requires an anteriorly positioned catheter. If there has been obvious contamination of the pleural space, this area should be washed liberally with sterile saline solutions in order to dilute the number of organisms present and flush out any extraneous clots seeded with them. The thoracotomy closure can then be completed in any standard fashion.

The ultimate prognosis in any given case of cardiac arrest will depend upon a host of factors, but the most important items probably are the duration and degree of cerebral hypoxia. True underlying myocardial disease will inevitably prejudice the end result. But, with attention to the details discussed above, dozens of patients can now be saved each year who would have previously been lost because of this abrupt and rarely anticipatable disaster.

Additional Postanesthetic Care. After the patient reaches the recovery ward, or his own room, unless he is fully conscious and active it is best to elevate the foot of the bed slightly. In addition to the reasons cited previously, the slope promotes evacuation of tracheobronchial secretions, discourages venous stagnation in the lower limbs and contributes to stabilization of the blood pressure. And, until the patient has resumed control of his faculties, it is important to remove excess mucous secretions regularly by the use of motor-driven suction which is applied intermittently through a catheter passed via the nose into the upper portion of the trachea. Pulmonary ventilation is promoted by turning the patient at intervals, urging him to cough and breathe deeply, or

Transfusions are given to balance losses in the operating room or recovery area and until the blood pressure and pulse rate are stabilized well outside any shock range. Sufficient fluids and electrolytes are supplied, foreseeing the total daily requirements. It is unwise to follow unqualifyingly the practice of giving only glucose in distilled water on the premise that sodium retention exists in the early postoperative period. Water intoxication, as manifest by weakness, paralysis, twitchings or even convulsions, can develop. Especially in children, this syndrome may appear abruptly on the first or second postoperative day if the child receives parenteral fluids totally lacking in sodium.

The Intensive Care Unit. As suggested earlier, all patients should be kept in the recovery room until fully conscious and free from the immediate effects of the operation. Some hospitals provide recovery room convalescent care until the patient is ambulatory and has little demand for specialized nursing. Other institutions have developed a subrecovery, or intensive care, unit in which specialized nursing is given to the patient after his transfer from the recovery room. Patients remain there until they are up and about and become minimal care problems. Here also the nursing staff becomes pre-eminently adept at providing a superior quality of bedside care and surgical procedures thereby are made safer for the patient. The availability in these areas of mimeographed postoperative order sheets for the doctors insures use of this list and will simplify the nursing routine and avoid overlooking important measures in this phase of postoperative care. A workable example of this arrangement is listed below.

Doctor's Postoperative Order Sheet

- 1 Vital signs q 15 min x 4
q ½ hr until stable then
q 2 hr x 24 hr
- 2 Position _____ Low Trendelenburg
_____ Semi-Fowler's
_____ Flat
- 3 Hemoglobin stat and in A.M.
- 4 Turn, cough, hyperventilate q. 2 hr x 24 then
q 4 hr until up and about
- 5 Suction trachea and aspirate pharynx p r n
- 6 Continuous gastric suction Check p r n (at least
q 4 hr) and irrigate as necessary with _____ cc
of _____ solution
- 7 Straight drainage to urinary catheter Irrigate
p r n. with sterile water.
- 8 Chart urine specific gravity b i d. 8-6
- 9 Weight daily litter _____ standing _____

of the incidence of atelectasis and postoperative pneumonia.

- 10 Sedation
 Morphine sulfate mg _____ q. _____ h. p.r.n. for pain
 Codeine mg. _____ q _____ h. for pain
 Demerol mg _____ q _____ h for pain
 Methadone mg. _____ q. _____ h. for pain
11. Penicillin _____ units q _____ h
 Streptomycin _____ gm q _____ h.
 Other _____
12. Fluid order: ADD:
 _____ cc. 5% glucose in distilled water
 _____ cc. 5% glucose in normal saline
 _____ cc. 10% glucose in distilled water
 _____ cc. 10% glucose in normal saline
 _____ cc. _____
- 13 Transfuse
 _____ cc. whole blood
 _____ cc. plasma
14. Blood loss _____ (chart on face sheet)
 15. Privileges _____
 16. Diet _____
 17. Chest x-ray stat. _____ A.M. _____
 18. Oxygen therapy:
 Tent _____ Nasal _____

Operative and Progress Notes. An accurately written, descriptive operative note should be placed promptly on the patient's chart by the surgeon. The first surgical assistant should write a note immediately and place it upon the chart to help in guiding the postoperative care. Such a note is not designed to replace, but rather to supplement, the formal operative report dictated by the surgeon. This summary by an assistant should mention the kind of anesthetic, type and location of the incision, pertinent details of the operative findings, principles of the operation carried out, amount of blood lost and transfused, type and location of drain, whether T tube or catheter was used and method and suture materials used in the closure. Any unusual technical problems or maneuvers should be appropriately identified along with the names of those doctors participating in this operation. Progress notes should be regularly added to this report, particularly during the first few days, and always whenever any new problem arises to mar the convalescence. Any significant changes in therapy should be cited. A specific note should be made when any drain is removed or allowed to remain in place at the time of the patient's leaving the hospital.

Finally, the notes should include a tabulation of the discharge instructions regarding diet, medications and recommendations for outpatient follow-up visits. In all these reports the emphasis should be upon clarity and brevity, without sacrificing relevant in-

formation and with minimal reliance on the use of eponyms, colloquialisms, initial-type abbreviations and other pet symbols indecipherable to future generations seeking knowledge from these charts.

Nutritional Requirements. Granted that a reasonably satisfactory preoperative dietary preparation has been possible, the total caloric needs of the postoperative patient are of small concern if no serious complications arise to prolong this period. As soon as peristalsis has been re-established and after removal of the gastric tube on the second to fourth day, the patient can be permitted a full liquid or soft diet. By the fifth to seventh day, the convalescent often accepts with gusto the solid fare which is offered and is soon thereafter ready for his hospital discharge. Those persons of a leaner habitus, after gastric resection, may feel the need of several small meals daily until the residual pouch and jejunum have become accommodated to the new status.* Since some of these patients tire easily from a moderate work load and are handicapped by their limited gastric capacity, if they will drink 1 or 2 ounces of salad oil, topped with fruit juice for increased palatability, two or three times daily, energy units will be provided with but little bulk.

Wound Healing and Wound Infection. The avoidance of wound complications begins with the patient's preoperative preparation. Especially important are the nutritional aspects, including the establishment of near-normal plasma albumin and hemoglobin values. A reduction in skin bacterial flora and sterilization of intestinal contents when the bowel is to be opened are also major considerations. Failure to meet these requirements may result in a seroma or hematoma, wound infection, disruption or evisceration. Wound infections occurring despite careful attention to these practices usually develop from unrecognized, gross contamination. Strict adherence to aseptic techniques by the operating personnel is essential, but it alone will not suffice. The more effective the precautions taken to control air-borne, bacterial-laden dust, the lower the incidence of infected wounds. The use in the operating suite of conditioned air, under slightly positive pressure, which has been filtered or, better yet, passed over an electrostatic par-

* Certain annoying postgastroctomy sequelae can be minimized or even avoided if the convalescent will not indulge in eating to satiety during each meal. Rather he should fill his stomach incompletely upon seven or eight occasions daily, taking care to select a diet high in calories for the volume consumed

ticle collector, or the use of a wet sorbent technique contributes to a reduction in wound seeding from air-borne bacteria. Freshly laundered canvas boots placed over the street shoes of every person who enters each operating room help also in this connection. Requiring students, nurses, anesthesiologists and surgeons to provide extra foot gear to be worn only in the operating rooms will serve to decrease the amount of contamination introduced from other areas. Whenever architectural arrangements permit, the normal ebb and flow of hospital traffic should be routed so as to by-pass the operating rooms.

During an operation the wound edges can be protected against excessive air-borne contamination, as well as against drying, by packs moistened with isotonic saline solution. Prior to closure, all wound layers should have a generous washing with this same solution to free them from the rich bacterial nutrient present in clot and tissue debris. Incisions which are so treated will then heal more kindly. Careful hemostasis throughout the operation, gentle handling of tissues, routine use of fine suture material, avoidance of mass ligation with its secondary necrosis, elimination of tissue dead spaces and anatomic dissections and repair respecting the residual blood supply, all contribute to a high incidence of primary wound healing.

A wound hematoma usually arises from careless hemostasis and a seroma from failure to obliterate dead space. Therefore, all incisions through a deep panniculus adiposus should be carefully approximated side to side as well as to the suture line of deeper fascia, from which fibrous layer it should not have been scraped—a practice unwisely indulged in by some. Rarely is a hematoma secondary to excessive postoperative anticoagulant therapy or to an unrecognized preoperative bleeding tendency. When one does develop, the area of involvement should be opened widely and the clot evacuated lest it become secondarily infected. If liquefaction has occurred, and if the volume of liquid is small, aspiration under sterile precautions followed by a compression dressing will sometimes suffice.

The routine use of retention sutures is a matter of individual choice. Often they are inserted under so much tension, however, that considerable loss of effectiveness occurs from subsequent necrosis and shearing of the tissue inside each loop. The technique suggested by Price for their placement and care seems more logical than many older methods.

Various materials are used in skin closures. If metal clips are employed, their removal in two to four days is wise in order to avoid local necrosis and unsightly postoperative blemishes. Broadly placed, coapting skin stitches may remain five to seven days. The smallest cutaneous stitches (5-0 or 6-0 silk), catching merely the epithelial elements, cause no disfigurement when left fourteen to sixteen days and they support the edges during the later stages of healing.

Whenever one is required to incise the skin in a person with a known tendency towards keloid, provision should be made to give x-radiation to this area unless other contraindications exist. On the other hand, incisions, and particularly vertical ones made in an area which has previously received heavy irradiation, are quite likely to heal poorly. The phase of vascularization in wound healing has thereby been impaired and consequently that wound will recover strength slowly. When a reasonable alternative site exists for the opening it should be elected.

The Contaminated Wound. Certain wounds are unavoidably contaminated during operation and may become seriously infected if closely primarily. Hence, delayed closure is advantageous in these cases. In this technique, the deeper fascial planes are approximated in the usual manner after a particularly thorough flushing with Ringer's or saline solution. Sutures are placed in the superficial structures but are not tightened. A dry gauze pack inserted loosely into the incision holds the wound edges apart and the entire area is covered with a dressing. After forty-eight to seventy-two hours, or even longer if the wound reaction and amount of drainage appear excessive, the pack can be removed and the individual sutures snugged up. A fresh external dressing is then applied. After-care is the same as for any wound. Provision for this interval of drainage averts any tendency to destructive burrowing by a pocketed infection and satisfactory healing has been assured both in the depths and at the skin edges.

Wound Disruption and Evisceration. Wound disruption is a serious sequel to impaired healing and occurs most commonly in midline abdominal incisions. Many factors predispose to this grave complication and in any one instance several may contribute. A knowledge of the more common mechanisms and how to avoid and/or overcome these hazards should help to reduce the incidence of this dangerous complication. The more

common factors contributing to wound disruption and evisceration are: (1) in the preoperative phase: (a) malnutrition, (b) hypoproteinemia, (c) chronic anemia, (d) massive recurrent hemorrhage with or without shock and (e) vitamin C deficiency; (2) in the operative period: (a) improper selection of suture material and/or defective suturing technique, (b) careless hemostasis, (c) an idiosyncrasy to absorbable suture material and (d) a midline or long vertical incision; (3) in the postoperative stage: (a) unusual abdominal wall strain from retching, persistent coughing, unrelieved hiccoughs, habitual sneezing, maniacal behavior with uncontrollable motor activity, (b) marked distention and (c) uremia.

Evisceration may occur through any type of incision. Also, it may occur whether the wound is closed with absorbable or non-absorbable sutures. However, much of the experimental and clinical evidence on this score suggests, but does not conclusively prove, that an oblique or transverse incision, closed with some form of nonabsorbable material, is less likely to be followed by wound disruption. Whenever, despite precautions to the contrary, the possibilities of wound disruption become real, a tightly applied spica arrangement of tape to the abdomen, extending from each groin to opposite costal margins, will lessen this likelihood. That advantage is somewhat counterbalanced by the concomitant interference of such tight strapping with normal ventilation and venous return from the lower extremities.

Violent straining or retching is likely to occur at times just as the patient is recovering from the anesthetic. During such episodes, if the sutures give way, an audible though muffled sound can sometimes be heard and this, of course, requires prompt investigation. When wound disruption has thus been suspected, most surgeons advise a prompt return of the patient to the operating room, where he can be reanesthetized, prepared and draped. The wound is then opened and the damage corrected with suture material having greater holding power. If knots have also become untied, particular attention should be given to "squaring" their replacements. Any subsequent postoperative episodes of struggling should be controlled with a small dose of Pentothal given intravenously. With the awakening thus cushioned, it can be made less violent and any unusual pain should be obtunded with narcotics. Persistent coughing may be controlled with ample sedation,

bearing in mind the greater likelihood of atelectasis during prolonged suppression of the cough reflex.

Unremitting, protracted hiccoughing exerts a severe strain on any abdominal wound. It may develop from a variety of harmless and inexplicable mechanisms but should suggest the possibility of such complications as gastric dilatation, peritonitis with subphrenic abscess, or uremia. Active treatment of any one of these which seems clinically likely should be given high priority for, with improvement of the underlying mechanism, the singultus often abates. In the absence of any specifically treatable etiologic mechanism, brief, periodic inhalations of 5 to 10 per cent carbon dioxide in oxygen will frequently interrupt the cyclic diaphragmatic spasm. Occasionally it may be necessary to block the phrenic nerve on the side involved.

Wound disruption and evisceration may occur at any time in the postoperative period, but customarily this regrettable occurrence takes place about the seventh day. The patient occasionally volunteers that "something gave away inside." If the skin remains intact, the condition is called wound disruption or dehiscence; if abdominal viscera are extruded, it is called evisceration. In cases of disruption, loops of bowel can sometimes be palpated under the cutaneous layers. Intestinal obstruction may occur from knuckling of a bowel segment into the separation and this may be the first recognized sign of wound disruption if the character of the initial wound drainage has been ignored. Severe localized pain in an incision, if accompanied by other evidence of mechanical bowel obstruction, should also suggest this possibility. In fact, ileus of otherwise unexplained origin may portend the development of this condition.

Shock may be present or rapidly develop in patients with evisceration and appropriate measures must be taken to provide transfusions promptly. It is a complication of calamitous proportions, the patient's life is in jeopardy, and these developments should be so viewed. Any sudden staining of the dressings with a profuse, pink, serous drainage is virtually diagnostic of wound disruption or worse, and makes it mandatory to remove all dressings and examine the incision. Before doing this, however, one should anticipate the probable need for special dressings and equipment. The surgeon should don sterile rubber gloves, a cap and a mask in order to provide the patient's wound with maximum protection from contamina-

tion A sterile covering should be at hand to lay over any protruding loops of bowel. In the event no viscera are visible or palpable, a few stitches should be removed with an aseptic technique and the depths of the wound probed or visualized to confirm the fact that dissolution has taken place. It is unusual not to find some area of disruption after a profuse typical serosanguineous discharge.

Treatment for wound disruption. Two methods of treatment are used for disruption and evisceration. For a patient who is a poor risk, has tenuous parietal fascia or is in profound shock, a conservative technique which can be carried out at the bedside is required. In the case of disruption of an abdominal wound, before either method is used, the passage of a nasal tube into the stomach to evacuate its contents will reduce the likelihood of regurgitation, endotracheal aspiration and probably pneumonia. Several preliminary applications of a topical anesthetic to the nasopharynx will minimize retching, and further disruption of the wound, during tube passage.

After the adjoining skin and wound edges have been prepared with an antiseptic, visible loops of bowel or other viscera should be cleansed thoroughly with liberal amounts of sterile isotonic saline solution and then returned to the peritoneal cavity. They should next be held in place temporarily with a sterile towel or a wide wad of gauze packing. If cooperation or relaxation is unsatisfactory, the patient can be lightly anesthetized and given as well a muscle-paralyzing drug intravenously. Soft rubber drains, 1 inch wide, should extend from the upper and lower extremities of the wound. The skin of the entire abdomen, flank and lower part of the chest is then cleansed with ether-dampened sponges and painted with compound tincture of benzoin. Long adhesive strips, which have been flamed for bactericidal purposes and to enhance their grip to the skin, are used to draw the wound edges together. These strips, stretching diagonally from gluteal fold to axilla, overlap each other from below upward. The defect is closed by developing traction toward the wound edges with each strip. With the inferior tape end stuck firmly, any tendency to retraction of the incision is countered by sliding the lateral tissues toward it. When the taping has been completed, the rubber drain should jut enough beyond the tape to carry away the discharge which might otherwise weaken the effectiveness of the tape's

holding power. Care is required to prevent a bowel knuckle from becoming incarcerated in the wound during this type of closure. The appearance later of signs of mechanical intestinal obstruction and localized pain would point to this possibility. Some ileus is liable to develop in most cases. The dressing, if properly functioning as a binder, should remain in place for at least two weeks, or longer if the patient has been poorly nourished. Although most of these patients will recover, a ventral hernia in the line of closure is likely.

A healthier patient with wound disruption will tolerate a return to the operating room where formal repair can be carried out. After a nasogastric tube has been inserted and connected to suction and arrangements made for whole blood transfusion, the patient is anesthetized and the abdominal wall is resutured under aseptic conditions. Steel wire tension sutures, tied down over a dental roll, as proposed by Price, work well. It is believed by those who favor the reoperation method that convalescence is shorter and intestinal obstruction is less likely to occur.

Drains. The use of drains after surgical procedures remains a controversial subject. Advantages can be cited on both sides of the question. The blood, plasma, bile, pancreatic juice or intestinal contents which come out denote the presence of this problem and suggest its need for treatment. Those who prefer not to use drains cite a lower incidence of such complications which they allege are due to the presence of these foreign materials. Opponents cite references also to the incompleteness of the "drainage" achievement.

Several types of simple drains can be used. The most common ones, Penrose tubing, soft-rubber catheters, rubber wicks and cigarette drains, rely on capillarity, gravity or slight pressure differences to effect the removal of fluid. Intra-abdominal drains customarily seal off from the adjacent viscera within forty-eight hours. However, one may continue to ooze fluid, such as bile, from a site of leakage for many days. In such a case, there should be no haste about removing it.

The other common type of drain is usually a more complex apparatus. It may have the form of a sump pump (Babcock), a double-lumen catheter (Chapin), air-vent suction (Wangensteen) or a multiple-holed catheter. These require mechanical suction to supplement the other forces of drainage and keep the selected area dry. They, too, eventually become walled off but serve to keep a site of leakage or a pocket drier, and thus facili-

tate healing. Suction, applied to a multiple-holed catheter positioned under the skin flaps in a neck dissection or a radical mastectomy, is a particularly effective technique for coapting widely reflected surfaces. The principal purposes of drainage are to prevent pocketing internally and to provide for external fistulization at the site of any leak. Once the drain has ceased doing either or both of these functions it should be eased out gradually, a few centimeters at a time. In this way, the tract can fill in from the depths. If all the tubing is pulled away at one time, the skin can seal before the depths are firmly united by healthy tissue. Pocketing and suppuration can still develop inside and complicate the later convalescence. Pain and localized tenderness will be noticeable in that area and may require subsequent re-opening of this channel.

Drains, particularly the firmer types, have been accused of abetting, or even causing, fistula formation when alongside an intestinal anastomosis. It is felt by those opposed to using them that the suture line is weakened by its proximity to a foreign body. Those in favor suggest that, if provision for such drainage had not been supplied when the suture line gave way, subsequent leakage and contamination would have dissected more widely while seeking a path to the outside. Drains serve a necessary purpose when used to maintain an evacuation track from an abscess pocket; their prophylactic, routine employment has little to recommend it.

Intestinal Fistula. The treatment of an intestinal fistula is usually easier the more distal the segment of bowel from which it arises. When the fistula develops from the colon, as after its resection or at an appendectomy site, healing is slow but steady if no obstruction is present. Constipation should be avoided. The more proximal the fistula in the small intestine, the greater the difficulties with water and electrolyte loss and the more destructive to other tissues are the bowel contents. The juices from a high intestinal fistula will rapidly digest away all tissues of the abdominal wall. These structures can be partially protected by the following plans:

1. Proximal control of the volume of intestinal contents by (a) limiting the oral intake; (b) passage of a Miller-Abbott or Grafton Smith tube down the gut to the fistula site with continuous suction on this tube and sufficient inflation of the distal bal-

loon to obstruct the lumen and thereby reduce the amount of discharge.

2. Control at the external opening by means of motor- or water-driven suction delivered through a multiple-holed catheter to the proximal limb of the fistula, thereby aspirating any accumulation.

3. Protection of the skin and adjacent tissues. Many kinds of paste are available for this purpose. While the dermis is intact, powdered aluminum rubbed into the area periodically will give considerable protection. Ladd's paste, brewer's yeast and tannic acid in lanolin also are sometimes effective in controlling tissue digestion.

4. Relief of any intestinal obstruction distal to the fistula which would otherwise perpetuate this complication. As soon as the patient's condition permits, the obstruction should be corrected by lysis of the adhesive bands, by a short-circuiting procedure, an intestinal resection or by some other means of intestinal deviation. If the fistula is located low in the intestinal tract, some of the material aspirated from the gut can be returned through a secondary gastric catheter to the stomach for partial reabsorption in the upper portion of the intestine.

Better drainage for the intra-abdominal ramifications associated with a fistula-forming episode can be obtained by placing the patient face down on a Foster or Stryker frame for specified intervals, as tolerated, several times each day.

The amount and kind of fluids and electrolytes necessary in these cases can tax the judgment of an experienced clinician, overall nutritional care is an equally difficult problem.

Atelectasis. Atelectasis can arise either from pulmonary compression by intrathoracic accumulations of blood clot, fluid or tumor or from obstruction of a portion of the bronchial tree by a mucous plug. The former mechanism rarely causes systemic symptoms other than a decrease in maximum ventilatory capacity and, occasionally, osteoarthropathy. The latter invariably provokes a clinical picture characterized by fever and some tachycardia. Imperfect expansion of the lung, whether massive, patchy or plate-like, occurring in the postoperative phase, is invariably due to obstruction of a bronchus or its distal ramifications by a mucous plug. Secondary factors which may contribute to the development of obstructive atelectasis include the following:

1. Hypoventilation can result from too pro-

found sedation but is more commonly secondary to pain in the operative site, which tends to limit the usual costal activity. A vertical upper-abdominal incision can contribute to this mechanism. As the ribs flare out with each breath, lateral tension pulls painfully on the wound edges. When pain is a restricting factor in the patient's ventilation, administration of an anodyne or providing a local anesthetic block of the area will often increase the depth of voluntary respiration.

2. Elevation of the diaphragm. An operation which weakens or paralyzes the diaphragm is commonly followed by some ventilatory impairment. After biliary tract surgery, atelectasis is not uncommon. Marked distention also interferes with normal diaphragmatic activity.

3. Aspiration of material from the intestinal tract. These contents irritate the tracheobronchial mucosa and provoke an inflammatory reaction, which may progress to pneumonia. In milder cases an increase occurs in the volume of local secretions, including mucus, and this too contributes to the high incidence of atelectasis after the accidental aspiration of intestinal contents. The aspiration of coagulable fresh blood is likewise provocative of atelectasis and pneumonitis. Its removal, even by bronchoscopy, can be troublesome.

4. Overatropinization. The administration of large doses of atropine inspissates the mucus and makes it more tenacious, thereby increasing the difficulty in bringing up these sticky plugs.

5. Anesthetic technique. Certain gases are more rapidly absorbed from the lungs than is air. Failure to "wash out" these mixtures at the end of an operation may contribute to an early appearance of atelectasis.

6. Existing pulmonary suppuration. In the presence of bronchiectasis or a lung abscess, pus, excess mucus and other secretions are already present and available. Loss of the cough reflex during anesthesia fosters retention of secretions and their spillage into adjacent pulmonary segments. The patient with pulmonary suppuration should spend a period several times each day before his operation in the head-down position and try to cough out as much as possible of the accumulated material. In such cases, bronchoscopy should also be done after the operation in order to insure thorough evacuation of the tracheobronchial tree, thereby minimizing the chances of postoperative atelectasis. The preoperative use of penicillin for

a few days in any person requiring an operation, despite the presence of coexisting pulmonary disease, will subsequently alter the tracheobronchial flora and likewise reduce the volume of secretions. The likelihood of postoperative atelectasis and bronchopneumonia will thereby be reduced.

7. Smoking. Cigarette smokers, particularly the heavy users, should be firmly urged to stop this habit for at least ten to fourteen days before any major elective surgical procedure. This interval will permit the tracheobronchial tree to recover, at least partially, from the irritation and excess mucus formation frequently associated with "smoker's cough."

Usually, the diagnosis of obstructive atelectasis serious enough to cause clinical symptoms is readily made from the chart and the physical findings. Its presence can be confirmed by a chest film. Though the pulse is rapid, the temperature is elevated often out of proportion both to the heart rate and to the apparent illness of the patient. The onset of fever is sudden, and commonly a temperature of 102° F. or higher is reached. On palpation of the trachea in the neck a deviation to the affected side can often be noted. The respiratory excursion is more limited over one side than over the other. On auscultation a few sticky rales can be heard, but either the usual breath sounds are absent or bronchial breathing is noted in the area of involvement. Cyanosis and dyspnea may be present. The x-ray picture is essentially that of an area of increased density on the affected side, with a lobar, mottled or platelike distribution, in association with elevation of the diaphragm, narrowing of the rib spaces and variable degrees of displacement of the trachea, mediastinum and heart to the affected side.

The treatment of atelectasis begins with attention to the predisposing and contributing factors. A lowered incidence and milder examples of this complication will result from such prophylaxis. Early ambulation probably helps avoid this complication by increasing the patient's ventilatory efforts. Once the process has developed, it is essential to treat it until it is cured. Failure to reinflate an atelectatic lung is likely to lead to chronic pulmonary changes and irreparable damage. Recurrent atelectasis in any person should alert the clinician to the possibility of intrinsic bronchial obstruction from an adenoma, carcinoma or nonopaque foreign body. Inducing the patient to cough, turning him in bed, hyperventilation with 5

to 10 per cent carbon dioxide in oxygen, and a sharp blow over the side of involvement are often effective means of dislodging a plug and expanding a collapsed segment. Auscultation of the chest should confirm the efficacy of the treatment or indicate the need for further active therapy. Endobronchial aspiration with a catheter attached to suction will make the patient cough and may pull out the offending mucus. In a particularly uncooperative or lethargic patient, translaryngeal suctioning of the trachea and bronchi can be facilitated by using a laryngoscope and an appropriately curved, open-tipped catheter. If these simple measures fail, bronchoscopic management is indicated. The end results of treatment are uniformly good when the disorder is corrected at an early stage of the process. If atelectasis proves intractable or has been neglected for many days, re-expansion is slower, and chronic, irreversible, pulmonary changes are more likely to occur.

Tracheostomy. A tracheostomy often has lifesaving advantages to bring into the management of specific problems incident to the control of tracheobronchial accumulations. Almost its sole drawback is the unattractive cervical scar as an aftermath, and this is minimized with a transverse incision. Tracheostomy is at times a wise prophylactic step; on other occasions, it is a well chosen supplemental method of retrieving a deteriorating situation. With regard to the former indication, it may complement the patient's convalescence when extensive surgery about the head and neck has temporarily abolished full control of the swallowing reflexes so that saliva or liquids are prone to trickle into the trachea. The tracheostomy permits easier and more effective aspiration of this airway-clogging, mucoid drainage before it can reach the pulmonary terminals. After deglutition has been recovered, this accessory vent for saliva can be abandoned. For other individuals whose prolonged efforts to rid themselves of excess secretions have led to exhaustion and a weakened coughing power, the addition of a tracheostomy is of slight surgical magnitude and considerable benefit. Its establishment can prevent drowning of a patient who is comatose, or profoundly debilitated, and insensate to the healthy cough-provoking mechanisms of foreign material in the respiratory tract. Moreover, when a tracheostomy opening is available, it simplifies the technique of bronchoscopy and thereby insures more ready use of this means to achieve the most complete and thorough

removal of all retained secretions. The ease of handling this problem afterward and the minimal disturbance to the patient so prepared are certain to encourage more frequent recourse to endoscopy. Whenever the eventual need for a tracheostomy appears likely it is best to establish one electively a few days prior to the major surgical procedure. A technically neater operation can then be done and the patient's respiratory tract will thereby have had adequate time to adapt to the altered humidity of the air which has by-passed the oronasopharynx. During this interval, it is particularly important to add moisture to the ambient air, preferably through cold-air humidifiers. Of course, if oxygen is piped directly into the tracheostomy opening, it should first be dispersed through water in an attempt to saturate it. Otherwise, desiccation and excessive tracheitis are likely to complicate and needlessly prolong the recovery from a tracheostomy.

Many persons otherwise well versed in postoperative problems exhibit a surprising reluctance to do a tracheostomy. They overlook or reject the possible contributions of this simple procedure until terminal and irreversible states of pulmonary congestion and pneumonia prevail. The patient is then being destroyed by infection, hypoxia and hypercapnia. Unless last-minute efforts at removing occluding plugs and pools are successful, he is doomed.

Distention. Distention may develop during the postoperative period in either of two forms: acute gastric dilatation or ileus, mechanical or inhibitory.

Acute gastric dilatation can appear after almost any operation, including thoracic and cardiac procedures. At times the procedure may seem almost too inconsequential to have caused this complication. Acute gastric dilatation appears also in patients with diabetes, during uremia and after fractures. Persons with compression fractures of the spine treated with a hyperextension frame or a cast are particularly likely to have this complication; the superior mesenteric artery-duodenal compression syndrome may play a role. After a variety of thoracic operations patients at times exhibit mild to moderate gastric dilatation.

The inexperienced house officer can hardly be condemned for thinking first of hemorrhage or embolism when called to see a patient who, a few days after a major operation, is obviously in a grave condition, appears slightly cyanotic, is dyspneic, has a

found sedation but is more commonly secondary to pain in the operative site, which tends to limit the usual costal activity. A vertical upper-abdominal incision can contribute to this mechanism. As the ribs flare out with each breath, lateral tension pulls painfully on the wound edges. When pain is a restricting factor in the patient's ventilation, administration of an anodyne or providing a local anesthetic block of the area will often increase the depth of voluntary respiration.

2. Elevation of the diaphragm. An operation which weakens or paralyzes the diaphragm is commonly followed by some ventilatory impairment. After biliary tract surgery, atelectasis is not uncommon. Marked distention also interferes with normal diaphragmatic activity.

3. Aspiration of material from the intestinal tract. These contents irritate the tracheobronchial mucosa and provoke an inflammatory reaction, which may progress to pneumonia. In milder cases an increase occurs in the volume of local secretions, including mucus, and this too contributes to the high incidence of atelectasis after the accidental aspiration of intestinal contents. The aspiration of coagulable fresh blood is likewise provocative of atelectasis and pneumonitis. Its removal, even by bronchoscopy, can be troublesome.

4. Overatropinization. The administration of large doses of atropine inspissates the mucus and makes it more tenacious, thereby increasing the difficulty in bringing up these sticky plugs.

5. Anesthetic technique. Certain gases are more rapidly absorbed from the lungs than is air. Failure to "wash out" these mixtures at the end of an operation may contribute to an early appearance of atelectasis.

6. Existing pulmonary suppuration. In the presence of bronchiectasis or a lung abscess, pus, excess mucus and other secretions are already present and available. Loss of the cough reflex during anesthesia fosters retention of secretions and their spillage into adjacent pulmonary segments. The patient with pulmonary suppuration should spend a period several times each day before his operation in the head-down position and try to cough out as much as possible of the accumulated material. In such cases, bronchoscopy should also be done after the operation in order to insure thorough evacuation of the tracheobronchial tree, thereby minimizing the chances of postoperative atelectasis. The preoperative use of penicillin for

a few days in any person requiring an operation, despite the presence of coexisting pulmonary disease, will subsequently alter the tracheobronchial flora and likewise reduce the volume of secretions. The likelihood of postoperative atelectasis and bronchopneumonia will thereby be reduced.

7. Smoking. Cigarette smokers, particularly the heavy users, should be firmly urged to stop this habit for at least ten to fourteen days before any major elective surgical procedure. This interval will permit the tracheobronchial tree to recover, at least partially, from the irritation and excess mucus formation frequently associated with "smoker's cough."

Usually, the diagnosis of obstructive atelectasis serious enough to cause clinical symptoms is readily made from the chart and the physical findings. Its presence can be confirmed by a chest film. Though the pulse is rapid, the temperature is elevated often out of proportion both to the heart rate and to the apparent illness of the patient. The onset of fever is sudden, and commonly a temperature of 102° F or higher is reached. On palpation of the trachea in the neck a deviation to the affected side can often be noted. The respiratory excursion is more limited over one side than over the other. On auscultation a few sticky rales can be heard, but either the usual breath sounds are absent or bronchial breathing is noted in the area of involvement. Cyanosis and dyspnea may be present. The x-ray picture is essentially that of an area of increased density on the affected side, with a lobar, mottled or platelike distribution, in association with elevation of the diaphragm, narrowing of the rib spaces and variable degrees of displacement of the trachea, mediastinum and heart to the affected side.

The treatment of atelectasis begins with attention to the predisposing and contributing factors. A lowered incidence and milder examples of this complication will result from such prophylaxis. Early ambulation probably helps avoid this complication by increasing the patient's ventilatory efforts. Once the process has developed, it is essential to treat it until it is cured. Failure to reinflate an atelectatic lung is likely to lead to chronic pulmonary changes and irreparable damage. Recurrent atelectasis in any person should alert the clinician to the possibility of intrinsic bronchial obstruction from an adenoma, carcinoma or nonopaque foreign body. Inducing the patient to cough, turning him in bed, hyperventilation with 5

100 to 200 cc. of a 10 per cent sodium chloride solution will often induce peristalsis. However, in any patient with persistent intestinal atony, it is imperative to exclude an intra-abdominal abscess as the precursor of this state before fruitless efforts are expended on its management by the various methods cited above. If a leak at a suture line is suspected, or an extra-enteric accumulation with a fluid level is discernible on an upright x-ray film of the abdomen, the first step, and sometimes the only one required to relieve the ileus, is to drain effectively this pocket of infection. Giving Congo red by mouth and finding this stain on the wound dressings aids in diagnosing the existence of an intestinal communication.

Subphrenic Abscess. Subphrenic abscess should be an uncommon complication after uncontaminated abdominal operations. A perforated ulcer or a ruptured appendix is the usual cause when there has been no antecedent surgery. Because of its often insidious onset, exploration of one or both subdiaphragmatic areas is frequently postponed. A subphrenic abscess may be anterior, posterior or on the left or right side. Combinations of these sites are, of course, possible, and rarely all four spaces can be infected simultaneously.

In a patient who has recently undergone a gastrointestinal operation or has had another intraperitoneal insult, fever of unexplained origin should arouse a suspicion of subphrenic abscess. The physical findings may be surprisingly meager, slow to appear or even inconsistent. To wait until all consultants agree upon the diagnosis is often to delay too long. X-ray and fluoroscopic study can contribute considerable information and support for a tentative diagnosis. At fluoroscopy, the diaphragm may be found to be elevated, sluggish or paralyzed. A fluid level pocketed under this leaf, and in a specific area outside the intestine, is virtually diagnostic. A small quantity of barium in the stomach, with the patient in the head-down position, will help demonstrate an abnormal separation between the diaphragm and the gastric pouch. The presence of pleural effusion with obscuration of the costophrenic sinus is also a helpful sign pointing at subdiaphragmatic inflammation, although this finding has many times erroneously been construed as having arisen from a pneumonic process. Plain and overexposed Bucky films in anteroposterior and lateral projections are useful to identify the true

nature of this complication and to locate the abscess as accurately as possible.

Recognition of a subphrenic abscess is at times difficult in the early postoperative period after abdominal surgery. Air is invariably present under the diaphragms following such operations and may remain easily identifiable for two weeks. Persistence, a tendency toward encapsulation and the appearance of a fluid level are significant signs pointing more to an infection than toward some benign residuum of the operation. However, a subphrenic infection need never show a fluid level and may merely remain as a smoldering granulomatous process. To complicate the clinical picture, also, the patient may be febrile from causes other than the subphrenic process. At times it may be impossible to make the categorical diagnosis of subphrenic process. Exploration is often justifiable then on the basis that further delay fosters the complications of diaphragmatic perforation, empyema, lung abscess, bronchial fistula, rupture and generalized peritonitis with a consequent rise in the mortality rate.

The principal purpose of operative treatment for a subphrenic abscess is to achieve continuous dependent drainage, whether the patient is reclining or standing. Except in the case of infection in the right posterior space, this goal is rarely realized. When the pocket has been definitely located there, the best approach is through the bed of the twelfth rib, as recommended by Ochsner. For an anterior accumulation and after an anterior drainage procedure, some residual puddling in the depths is almost inevitable whenever the patient is supine. The prone position will, therefore, provide better drainage. It should be sought by maintaining the patient on a Foster or Stryker frame for as long a period each day as tolerated. Occasionally, a secondary posterior opening will be required to complete the drainage process. The preferred approach to an anterior encapsulation is that of Clairmont. Through a subcostal incision extraperitoneal dissection is carried down to the area of involvement and this is then entered. In both the anterior and the posterior approaches, extraperitoneal dissection should be utilized until the abscess is reached and evacuated. The overlying surfaces become agglutinated around the pocket and the free peritoneal cavity is sealed off by the adjacent inflammatory reaction. Transperitoneal drainage, on the other hand, is much more likely to

rapid, thready pulse and cool extremities covered with perspiration. However, if percussion of the upper abdomen elicits tympanitic sounds over a wide area, the presumptive diagnosis can be established by passing a gastric tube and releasing a gush of air and then a considerable volume of coffee grounds-appearing fluid. Copious vomiting may never occur as a warning sign for this complication. Rather, the patient repeatedly regurgitates small amounts of hematin-tinged fluid. Meanwhile, enormous quantities, several liters, can accumulate in the stomach and the underlying problem remain unrecognized. In fact, enough gastric juice may already have become sequestered in the stomach to leave the patient hypochloremic. With decompressive relief from the gaseous distention of the stomach and restitution of adequate quantities of salt and water and occasionally after a transfusion of plasma or blood, the patient usually makes a rapid convalescence. In a few hours, it may be difficult to realize that only a short time before the patient's condition was critical. Failure to recognize and treat acute gastric dilatation can, on the other hand, lead to a fatal outcome. Prophylaxis is as effective as therapy and has the added advantage of reducing the opportunity for a missed diagnosis. The routine use of a continuous indwelling gastric siphonage system following major surgical operations will virtually abolish postoperative dilatation of the stomach. When the patient becomes ambulatory or intestinal activity is restored, the possibility of this complication developing becomes minimal and suction should be discontinued.

Meteorism is truly the bane of surgeons and methods helpful in its therapy are worthy of emphasis. After intra-abdominal manipulation, normal peristalsis is inhibited for periods of up to several days. Any extensive degree of traumatic, chemical or bacterial peritonitis will contribute to the duration of this effect. For instance, a mass ligation technique which leaves behind clumps of necrotic omentum is liable to curtail intestinal activity. Local inhibitory effects are aggravated further by any marked increase in bowel diameter. Accumulations in the gut contributing to the distention are gaseous material, of which at least 70 per cent is swallowed air, the unabsorbed residue from the oral intake, plus saliva, gastric and pancreatic juices, bile, succus entericus and bacteria and their end products.

Apparently the predisposing mechanisms

for some degree of ileus are present in every abdominal procedure. The alternatives are either to interrupt the cycle leading to clinical ileus or accept a high incidence of this complication and rely on nature and the patient's durability to cope with it. A nine-holed Wangenstein gastric catheter attached to continuous suction equipment, used routinely throughout the procedure and until intestinal activity is restored two to four days afterward, will regularly avert this complication, unless it is caused by peritonitis. The equipment should, of course, be properly serviced and set in working order prior to the operation.

Those with experience in the management of this problem are inclined to agree that it is easier to prevent ileus than to overcome it. In the treatment of adynamic ileus, the Miller-Abbott tube, or, preferably, the Grafton Smith modification, becomes really effective only after having been passed through the duodenum, a maneuver requiring patience and skill. However, in some patients it may be impossible, for all practical purposes, to intubate the small intestine. Another drawback occurs once distention is permitted to develop—then the differentiation between inhibitory (adynamic) and mechanical ileus must be made. If localized pain, a mass, rebound tenderness and leukocytosis are present, a strangulating obstruction may be the cause. Pain in the back of sudden onset and with the above signs and symptoms favors this diagnosis.

It can be observed that marked abdominal distention immobilizes and elevates the diaphragm, contributing thereby to a greater incidence of atelectasis and other pulmonary complications. The development of marked abdominal distention also favors venous stasis in the lower extremities. It is a reasonable presumption, therefore, that this state increases the likelihood of phlebothrombosis and, hence, embolic phenomena.

A few cases of postoperative ileus are well-nigh intractable, but most will eventually respond to one or more procedures, including intestinal siphonage, splanchnic block or spinal anesthesia and the use of Pituitrin or Mecholyl. Hypokalemia will induce intestinal atony and hence contribute to the development and perpetuation of ileus. Ambulation, when feasible, is one of the best means of inducing peristaltic activity and will usually prove helpful unless chemical or bacterial peritonitis exists. When no systemic contraindication to an augmented salt intake is present, an enema of

discharge date is perhaps as beneficial a method as we have for routine prophylaxis against these complications. Just why early ambulation appears to be of such little value in preventing venous complications is puzzling, but that this is the case has been concluded from various collected studies.

Ambulation is most effective when started within the first twenty-four hours after an operation, but this schedule should not be inflexible. Those patients who are too ill or enfeebled to get out of bed before a major operation can hardly be expected to do so shortly afterward. It is wisest to modify the regimen so that as the patient assumes an upright position he experiences no serious blood pressure change. A preliminary trial of dangling the feet for a few minutes may indicate the individual's tolerance to resumption of the vertical habitus. Any tendency toward syncope is cause for temporizing and returning the patient to bed; then gradually, after recovery from that episode, he may again attempt an erect posture. Once he is up, he should be encouraged to exercise and then return to bed. If exercise is tolerated, he can try to walk more often and farther each day. At first, he may be unable to attempt more than a few steps in the morning and again in the afternoon.

"Ambulate" is a term meaning "to walk" and it is the surgeon's responsibility to confirm the fact that nurses so interpret this order to the patient. It is an error to consider early ambulation as synonymous with getting the patient out of bed and into a chair as soon as possible after an operation. Keeping him "angulated" there any length of time instead of having him up and about is an abuse of proper ambulatory management and can cause harm. An elderly patient who falls asleep in the sitting position is prone to orthostatic hypotension. Confusion, disorientation, syncope and concussion, fractures or other forms of severe trauma may result. Early ambulation, properly supervised, is decidedly beneficial and should be an integral part of any comprehensive program for postoperative management.

Fever. Although fever in the postoperative patient may arise from a variety of single factors, certain probabilities are more frequently causative and also more likely to exhibit revealing clues. The patient deserves a careful evaluation of these significant signs and, in the instance of a sharp rise of the temperature line, it should not be construed as ample treatment by the house officer merely to order doubled the dosage and

variety of antibiotics. In a patient with an elevated temperature, the more likely indications of its cause will probably be found in the lungs, urinary tract, operative area, veins of extremities, including the sites of intravenous therapy, and in an abnormal systemic reaction to drugs. The patient with pseudomembranous enterocolitis can also exhibit fever even before the stage of diarrhea.

Febrogenic complications are more apt to attract clinical attention at certain periods in the postoperative phase. Pulmonary problems (atelectasis, pneumonia), when they do occur, are more often noticed within the first twenty-four to forty-eight hours. A bit later urinary tract infection becomes manifest, particularly if the catheter has just been removed or had to be reinserted. Leakage from a suture line is rarely apparent before the fourth or fifth postoperative day. Wound infection and disruption begin to appear on the sixth to tenth days; thrombophlebitis tends to come on about then or slightly later. Drug idiosyncrasies can be the reason for a febrile course at any time, even well into the recovery interval.

A history of burning on urination, frequency and urgency with voiding, and/or renal tenderness points strongly to involvement in the urinary tract. The microscopic examination of a centrifuged fresh specimen is then indicated; a positive urine culture from a catheterized, or midvoided, specimen will clinch that consideration. Also, any male patient who is either repeatedly catheterized or wearing an inlying tube should have a careful genitorectal examination to identify the presence of epididymitis or prostatitis as a cause of fever.

Complete examination of the operative area is awkward sometimes, but this should not serve as an excuse for failing to uncover and carefully inspect the wound itself. Clean surgical incisions should be free of the usual signs of an acute inflammatory reaction. An incision that shows signs of inflammation should be suspected of harboring an infection. Elective incisions should heal kindly and remain free of exquisite tenderness to the sterile gloved, careful, palpating finger. If in doubt, a responsible person should remove aseptically a few sutures and gently part the superficial tissues so as to reveal any purulent loculus. If an abscess is present, adequate drainage will ease the pain from the patient's incision, valuable time will be saved and the morbidity thus shortened. Should the area prove clean on inspec-

contaminate uninvolved visceral and parietal surfaces, thereby increasing the morbidity. With care, only infrequently will it be necessary to use this less desirable avenue to a subphrenic abscess.

A fact about the subphrenic abscess problem which has become increasingly evident is the relatively small contribution that antibiotics have made to a reduction in the mortality from it. The pace of the disease may be slowed and the onset masked to some extent, but few abscesses are cured by chemotherapy alone. In fact, it is questionable that the patient's recovery is materially hastened, after ample drainage, by antibiotics. In general, convalescence remains protracted, while the body slowly absorbs and heals the abscess cavity.

Parotitis. Acute inflammation of the parotid gland, except in association with mumps or secondary to sialolithiasis, was more commonly seen in early times as a postoperative complication than it is now. The current liberal use of antibiotics, the giving of fluids orally after an operation and the avoidance of dehydration through better attention to the fluid and electrolyte requirements, all combine to reduce the incidence of parotitis. The most likely candidate for its occurrence is the elderly, debilitated, patient undergoing a febrile convalescence, poor in oral hygiene and exhibiting a parched mucous membrane. The parotid lesion is more often initially unilateral, with a subsequent occasional appearance on the opposite side. It is characterized by local tenderness and swelling, some trismus and expressible pus from a swollen, inflamed Stensen's duct. Fluctuation is difficult to elicit because of the gland's fibrous septa and tense capsule and the infection's deep location in the gland. As a rule, early parotitis will respond to antibiotics and to correction of the predisposing mechanisms. Deep x-ray or radium therapy to the area gives satisfactory results if abscess formation has not occurred. Early treatment is particularly effective. The development of portable deep x-ray therapy units which can be brought to the bedside has increased the usefulness of x-ray management. If abscess formation is suspected, incision and drainage parallel to the main fibers of the facial nerve are in order. In a few cases, the condition is fulminant and progresses rapidly unless actively treated. The high mortality ascribed to this condition in the past may well be related to the appearance of this complica-

tion as a terminal incident in very poor-risk patients.

Ambulation. Renewed interest has developed in Ries' recommendation, made a half-century ago, of early ambulation. At the time his idea evoked no widespread acceptance and it was only tardily submitted to a limited practical trial by a few clinicians. Now, many subscribe to a program for early ambulation. In cases of sepsis, however, conservatism is probably still indicated. In the presence of purulent foci, or of widespread infection, any undue activity is more apt to disseminate the process. Rest rather than exercise is indicated until the inflammatory process is under control. Otherwise, many leaders in obstetrics, gynecology, neurosurgery, thoracic surgery, orthopedics and general surgery now urge their patients to be up and about soon after major operations. Although there has been a growing acceptance of this idea, it remains difficult to identify precisely the contributions of early ambulation to better patient care. Some of the good effects are unquestionably obscured by the benefits from antibiotics, superior anesthetic agents, more liberal transfusions, better nutritional preparation, the more physiologic management of water and electrolyte problems and yet other factors.

Over and above any ambiguous contributions of early ambulation, several considerations, however, appear to have merit. (1) Pain disappears more promptly from the operative site and is usually less exquisite. (2) Certain annoying postoperative sequelae occur less frequently and in a milder form. (3) The patient's morale is better and his psychologic reaction following the operation is healthier. This is of special concern and benefit in care of the elderly patient, for once he is up and about, it is easier to arouse him from self-pity and discouragement. (4) The incidence of serious complications is not increased. For example, the recurrence rate seems no greater if early ambulation is practiced after herniorrhaphy. (5) The duration of hospitalization after a major operation is shortened, convalescence at home is hastened and, hence, the over-all economic loss to the patient is reduced.

The incidence and severity of thrombophlebitis and phlebothrombosis remain approximately the same, unfortunately. Wrapping the patient's legs, from foot to mid-thigh, with elastic bandages before surgery and rewrapping them at least daily until the

Management of Fluid and Electrolytes in Surgical Practice

By BERNARD ZIMMERMANN, M.D.

BERNARD ZIMMERMANN was born in Minnesota and received his education at Harvard University and Medical School. He spent time in research in endocrinology and metabolism before beginning his surgical training, which he received at the University of Minnesota. He has retained his interest in investigations of the relation between endocrinology and electrolyte and fluid balance in surgical patients.

Most of the ventures which have resulted in present-day surgery would not have been successful, or perhaps even attempted, had it not been for the concomitant development of an extensive body of information pertaining to the support of the physiologic needs of patients following extensive surgery. Radical visceral cancer surgery, modern thoracic surgery and cardiovascular surgery exemplify the priority of such fundamental knowledge. Many of the early steps in this field were taken by pediatricians, such as Gamble, who investigated fluid and electrolyte losses from the body in abnormal states and the chemical alterations which losses produce on the composition of the body fluids. These alterations mainly concerned sodium, chloride and bicarbonate and it took another pediatrician to indicate the importance of derangements of intracellular composition. Thus, surgeons, following the work of Darrow on potassium losses in infantile diarrhea, soon appreciated the significance of this ion in the correction of postoperative electrolyte deficits. Another

aspect of the development of basic knowledge which is now applicable to the patient following major surgery is the newer understanding of those metabolic effects which accompany all major traumatic incidents to which the human body may be subjected. From the work of Cuthbertson and Albright and the observations made on animals by Selye and his colleagues, the concept has been established that the patient who has undergone major surgery, regardless of the type of operation, is vastly different from the normal individual. His need for some substances is far greater, his tolerance for others is less and the problem has become much more complicated than the simple calculation of requirements from the difference between what goes into the body and what comes out.

Physiologic Characteristics of the Postoperative Patient. Trauma of a degree comparable to that represented by major surgical operations results not only in rather characteristic alterations in metabolism but also in gross changes in such tissues as the

tion, the convalescence will not have been materially prolonged, the gaping wound edges can either be snugged together with flamed tape or resutured, a local anesthetic being used. Deeper-seated purulent accumulations may reveal themselves in the pelvis upon rectal or bimanual examination. Abnormal aggregates of air and fluid lying just beneath the diaphragm are quite recognizable on upright films of the abdomen. An unusually high diaphragm and pleural effusion may be clues to the existence of this process.

Displaced loops of bowel about a constant area of opacification and in association with a partial small bowel obstruction or clinical ileus are strongly suggestive signs of an intra-abdominal abscess. Localized and abnormal degrees of tenderness over this suspect area will influence one's decision to explore and drain that locus-extraperitoneally, if at all feasible.

Thrombophlebitis, other than the traumatic or chemical variety secondary to a venoclysis, is likely to produce significant elevations of the patient's temperature. This complication or phlebothrombosis should be actively and carefully sought for in any person with mild to moderate fever, the exact origin of which remains annoyingly obscure. Moreover, promptly instituted therapeutic procedures such as decreasing the blood coagulability are in order. Certainly, the appearance of a positive Homan's sign, or merely of deep calf pain on palpation and especially if associated with prominent ante-tibial veins in a recumbent patient, suggests strongly this diagnosis.

Abnormal drug reactions, although uncommon, work their consequences onto the temperature chart with sufficient frequency to disrupt even the smoothest running service. Whenever the magnitude of the rise in the patient's fever is quite out of proportion to the pulse response and other more likely causes have been excluded, a medication reaction moves from the realm of a possibility to a probability.

mains obscure. It is known that, unlike the so-called glyccorticoids, aldosterone does not require the presence of the pituitary for its mobilization. Nevertheless, under appropriate circumstances ACTH can cause aldosterone to be secreted so that the action of ACTH can be described as a sufficient but not necessary factor for the release of salt-regulating hormones. Sodium restriction causes a greatly increased output of aldosterone, but it is probable that the effect of sodium restriction is mediated through changes in circulatory volume rather than reduction in the sodium levels. Reduction of sodium concentration by itself apparently has nothing to do with aldosterone release.

The work of Bartter would indicate that the most important single mechanism is reduction in blood volume and, more specifically, the volume of blood which is perfusing the arterial circulation. Further, sodium-retaining hormone is mobilized through the activity of some type of "volume receptors" activating hypothalamic centers which, in turn through a separate trophic mechanism, stimulate the appropriate portions of the adrenal. The resulting retention of sodium is a mechanism for protecting the circulating volume. It is not entirely clear, however, that all operations which are followed by an increase in aldosterone output and sodium retention involve any threat of reduction of blood volume or cardiac output. Therefore, other mechanisms must be considered. It has now been shown, for example, that a rise in serum potassium stimulates the adrenal gland to secrete aldosterone and, since potassium mobilization is a rather constant concomitant of major surgical procedures and other forms of tissue injury, we must consider that this may be an important underlying mechanism which is mobilized in order to aid the kidney in clearing the circulation of an excessive potassium load.

Although it appears that the role of aldosterone must be of great importance in the regulation of mineral balance immediately following operations, it is by no means clear that this substance is totally responsible for the over-all change in mineral metabolism which occurs in the postoperative course. Aldosterone, as measured in the urine of these patients, appears early in the postoperative course and almost uniformly returns to basal levels in two to three days. Positive sodium balance, on the other hand, may persist for six or seven days and almost regularly obtains after the aldosterone levels are normal.

This picture of an early rise, followed by a rapid decrease in aldosterone in the face of more prolonged positive sodium balance, is illustrated by the course of the patient shown in Figure 1. The investigation of other salt-regulating hormonal mechanisms is, therefore, being actively pursued at the present time. Clearly, the release of aldosterone is not caused by a single stimulus for which surgery acts as a trigger but is the result of a complicated interplay of factors involving the circulatory system and the central nervous system, as well as the changes in electrolyte concentration which result from injury to tissues.

It is likely that none of the metabolic responses to surgery are exclusively regulated by the endocrine system and it must be remembered in this connection that hormones in general only catalyze and do not originate metabolic and membrane-transfer phenomena. There is a considerable body of evidence suggesting that in both man and animals, devoid of adrenal glands but maintained on constant amounts of cortical replacement, nitrogen excretion, sodium retention and potassium loss can all be induced by the imposition of nonspecific stress. This strengthens the notion that the underlying pathways for these reactions exist in the basic enzymatic machinery and do not depend exclusively on an acceleration in en-

Figure 1. The course of the blood levels and balance of electrolytes as related to the urinary excretion of aldosterone and 17-hydroxycorticoids following a typical operation.

formed elements of the blood and the lymphatic system, the thymus and the adrenal glands. Nitrogen and carbohydrate balance are altered so that blood sugar tends to be elevated, glucose tolerance is decreased, glycosuria is not uncommon and, in instances in which marginal glucose tolerance exists, transient or even permanent diabetes may be precipitated by a major surgical procedure. Along with this, the balance of nitrogen becomes negative as measured by an increased output of nitrogen in the urine and a relative inability of the organism to utilize exogenous amino acids for the synthesis of structural body proteins. Sodium and chloride tend to be withheld from the urine and, in the immediate postoperative phase, urinary concentrations of these two ions may drop to almost zero even when the amounts given are greater than that normally necessary for daily replacement. Urinary potassium concentrations, on the other hand, are regularly elevated. Potassium balance becomes negative and that this urinary excretion of potassium is not entirely the

can be proved by sodium-to-nitrogen ratio rather than that which characterizes the interior of the cell.

The postoperative patient is frequently oliguric, even in the absence of preceding shock or other factors which might be expected to predispose to disturbances of renal function. More consistently than this, however, postoperative patients display intolerance to water. This implies that their diuretic response to a water load is impaired so that they excrete excess water sluggishly and may suffer the consequences of dilution or hydemia before the kidneys are able to respond to an excess of administered fluid.

These metabolic alterations are associated in patients following surgery, and in experimental animals following trauma, with certain morphologic changes including depression of the number of lymphocytes and the eosinophils in the blood, involution of the lymphoid tissues such as the thymus and enlargement of the adrenal cortices. The underlying factor in these morphologic changes and certain of the metabolic effects is the production of an increased amount of hormones by the adrenal cortex. It must be recognized, however, that no single mechanism is likely to be responsible for all of the metabolic phenomena which characterize the response to surgery. It is likely that these reactions have a definite protective effect on the economy of the organism

although the nature of this protection requires further investigation.

response to stress. It is very clear that the pituitary rapidly secretes an increased amount of adrenocorticotrophic hormone to which the adrenal responds with the output of one or more metabolic

pituitary and centers in the hypothalamus, the relationship of which to the hypophysis appears to be a humoral rather than a neural one. It is likely that more than one mechanism is responsible for the discharge from these hypothalamic centers.

At least three types of hormones are known to be produced by the adrenal cortex. As defined by their function rather than their chemistry, these include the glucocorticoids which are responsible for regulation of carbohydrate protein metabolism, the androgens which in addition to masculinizing balance, and

dominantly sodium and potassium balance, and processes capable of profoundly altering organic metabolism are mobilized by the adrenal gland following surgery has been demonstrated by the finding of increased hormones of this type in the postoperative urine, as well as the presence of 11-oxy-17-hydrocorticoids in the blood. The consistent occurrence of eosinopenia following surgery also suggests the presence of this same type of hormone, although less significance can now be attached to the fall in eosinophil count than was suggested by the early experiments relating eosinophil depression to adrenal cortical activity.

The endocrine mechanisms for postoperative alterations in sodium and potassium regulation are still not completely understood. Although the relationship of 11-oxy-17-hydroxycorticoids to alterations in organic metabolism has been recognized for a long time, the endocrine substance responsible for regulation of sodium and potassium balance was not known until the recent discovery of aldosterone and the demonstration of its presence in various pathologic states associated with sodium retention.

The recent findings of increased amounts of this hormone in the urine of postoperative patients leaves no doubt that it is mobilized by surgery. The intermediate mechanism, however, which results in the stimulation of aldosterone production by the adrenal re-

electrolyte physiology must take into account all the major fluid spaces and the nature of the boundaries which separate them.

The extracellular fluid is composed of the blood plasma and the interstitial fluid. Values for this volume vary from 17 to 20 per cent of the body weight depending upon the method used for determination. More recent methods give lower values. Older determinations indicated that the total body water was about 70 per cent of the body weight. Measurements using deuterium oxide suggest average values of around 61 per cent for men and 52 per cent for women.

The blood plasma and interstitial fluid are essentially the same in composition except for the difference in protein concentration which results from the relative impermeability of the capillary to these large molecules. The composition of the cell fluid, on the other hand, differs radically from that of the extracellular environment. Whereas the sodium is the major extracellular cation, potassium occupies this position in the cell where phosphate is the predominant anion. Despite this, it is not true as was once believed that sodium is completely excluded from the cell. A definite amount of sodium ion constitutes a portion of the intracellular ionic structure and there is a great deal of evidence that this quantity may be increased under circumstances of injury and disease. It must also be recognized that the relative exclusion of sodium from the cell is not a matter of permeability of the cell wall. Individual sodium ions have been shown by tracer techniques readily to permeate the cell membrane, showing that maintenance of an unequal gradient is not a matter of permeability but an active process requiring the expenditure of metabolic energy. The perpetuation of these unequal concentrations is, therefore, a function of normal cells and a characteristic of life as significant as the utilization of oxygen and the production of carbon dioxide. It is typical, moreover, of "sick cells" that these gradients tend to break down and the intracellular concentrations approach those of the surrounding medium.

The values mentioned above for the volumes of the intracellular and extracellular compartments describe the situation in the normal individual. It is of some importance to consider the factors which regulate these volume relationships. The critical quantity in this regard is the extracellular sodium, for the intracellular volume does not depend

on the available water of the extracellular space but rather its total ionic concentration. Since sodium exists in largest concentration, the level of this ion is the most important controlling factor. A decrease in sodium ion concentration results in a movement of water into the cells with consequent enlargement of the intracellular volume, and similarly an increase in sodium concentration results in cellular dehydration. Such changes in cell water have profound functional implications and the central nervous system is particularly sensitive to them. Consequently, changes in tonicity underlie many of the clinical manifestations for which deviations of water and electrolyte balance are responsible.

Requirements of Surgical Patients. The initial consideration for fluid replacement is the basal requirement for the human being who, for reasons of disease or surgery, is denied the oral route of alimentation. The minimal quota for an adult must take account of an insensible loss through the skin and lungs ranging from 600 to 1000 cc. and an anticipated urine output of 1000 to 1500 cc. Insensible losses may, of course, be far greater than this, particularly in the circumstances of fever or prolonged surgery under heavy cloth draping.

It must also be appreciated that exogenous water is not the sole source of fluid for extracellular hydration in seriously ill patients. Moore has pointed out that in severe injury or chronic illness as much as 1000 cc. of water can be mobilized daily from endogenous sources. This is made up of cell water (about 700 cc. per kg. of lean tissue), oxidation of protein (about 150 cc. per kg.) and of fat (1080 cc. per kg.). Accurate studies on patients with anuria, in whom the control of water administration must be extremely precise, have shown that as little as 400 to 500 cc. of exogenous water may sometimes be required.

The factors of insensible loss and endogenous water are not only variable but highly unpredictable and this is the reason for the unique value of the body weight in assessing states of hydration. In addition, therefore, to measure accurately the fluid intake and output, surgical patients should be weighed daily on a balance which is accurate to 0.1 kg. and the weight recorded on the chart along with the fluid balance data. In patients too ill to stand on a scale, this can be accomplished by a balance which utilizes a litter upon which the patient is lifted from his bed.

docrine function. Nevertheless, the importance of the endocrines for preservation of life under circumstances of systemic stress is adequately demonstrated by the almost uniformly fatal results of even minor operations inadvertently carried out on patients with adrenal insufficiency.

A seeming paradox exists in the fact that during the period following extensive surgery, when sodium and chloride are rigorously withheld from the urine, plasma levels of these ions are commonly reduced. The question as to whether this reduction of plasma levels represents only the addition of salt-free water which is not excreted, or must be explained in part by some presently undefined sequestration of sodium and chloride ions, remains debatable. A more significant fact, however, is that in patients following operations the administration of salt-free solutions, such as 5 per cent glucose, is followed by only sluggish diuresis and by reduction of plasma electrolyte concentrations. Administration of the same amount of glucose solution to normal individuals, or preoperative patients, results in almost no change in the plasma concentrations. Various lines of evidence suggest that this diminution of urine output in the early postoperative course is related to antidiuretic activity of posterior pituitary origin.

In the normally hydrated patient, the surgical operation produces physiologic effects similar to those of Pitressin, urine flow decreases, urine osmolality increases and serum osmolality decreases, as does the "free" water clearance (C_{H_2O}), which is defined as the difference between urine flow (V) and the osmolar clearance ($\frac{U_{osm}}{P_{osm}} \cdot V$), so that.

$$C_{H_2O} = V - \frac{U_{osm}}{P_{osm}} \cdot V$$

This value is negative when water is being conserved at the expense of solute.

It is important to realize that these observations regarding water and solute output following surgery are not by themselves unequivocal evidence of antidiuretic activity. They can only be so interpreted if glomerular filtration is shown to be either constant or increasing, a circumstance which has not been met in most studies of the subject. Recent experiments have shown, for example, that even in the animal with experimental diabetes insipidus, a hypertonic urine can be produced by restriction of renal blood flow and glomerular filtration. The

Figure 2 The course of serum and urine osmolality as related to excretion of biologically measured antidiuretic hormone excretion following a typical operation

importance of serious alterations in renal blood flow following major surgical procedures cannot be disregarded.

The second source of evidence for antidiuretic activity derives from the measurement of the antidiuretic potency in experimental animals of polypeptides extracted from the urine. Though this biologic assay also has both practical and theoretical drawbacks, no chemical determination is presently available. Despite the limitations of both approaches, the weight of evidence indicates that even slight trauma is an important stimulus for antidiuretic activity and that this stimulus can act without regard to the normal "osmolar receptor" mechanism through which the tonicity of the extracellular fluid is normally controlled. This produces a paradoxical situation of increasing antidiuretic activity occurring while the plasma is becoming increasingly dilute. The course of biologically measured ADH excretion and the urine and plasma osmolality following a typical surgical operation is illustrated in Figure 2.

Fluid Compartments; Their Boundaries and Constituents. The tendency of clinicians to describe abnormalities of fluid and electrolyte physiology in terms of plasma values results only from the relative simplicity with which a sample can be drawn from the circulating blood. Although blood values are obviously of great importance, any rational consideration of abnormalities of fluid and

when lost from the body in significant amounts. Bile is more alkaline than plasma though its sodium-to-chloride ratio is not nearly so high as that of pancreatic juice. Intestinal fistulae, except for high ones, tend also to produce acidosis because of relatively greater sodium losses. Most aspirates from tubes and fistulae are of mixed, and frequently of undetermined, origin and it may be occasionally necessary to make actual measurements of solutes in the secretions in order effectively to provide for their replacement.

For common situations, average values for gastrointestinal fluids based on previous experience are adequate and Table 1 and Table 2 from the work of Lockwood and Randall present some mean concentrations of sodium, potassium and chloride for typical secretions. Reference to these tables is useful in approximating the requirements in average cases. To replace the acid secretion from a normal stomach, it is usually only necessary to use sodium chloride solutions even though this may entail giving an excess of sodium ion. Since a normal kidney excretes the sodium, acid salts such as ammonium chloride are rarely necessary, except when serious distortions of body chemistry have become established. However, in the management of pancreatic, biliary and intestinal fistulae where sodium loss predominates, replacement cannot be achieved by the use of sodium chloride alone and alkaline solutions such as sodium bicarbonate or lactate are necessary. In this connection, it will be recalled that the plasma is normally alkaline. The administration of sodium chloride alone is, therefore, an acidosis-producing procedure although the kidney can normally compensate for this effect.

The question of replacement of magnesium ion and the rare occurrence of magnesium deficiency syndromes are matters of considerable current interest. Although the intake of magnesium in the average diet

is said to be around 300 mg. per day, the normal individual appears able to conserve this ion effectively in the presence of deficient intake. Nevertheless, the magnesium content of gastric aspiration fluid is 10 to 20 mEq. per liter and there is some evidence that magnesium behaves partly like potassium with respect to adrenal function in that mineral-regulating corticoids accelerate its excretion. One would expect, therefore, that major surgery, particularly gastrointestinal surgery, would present a threat to the magnesium stores. Unfortunately, few balance studies directed toward elucidating the behavior of magnesium in response to surgery have been made, largely because available methods have not been sufficiently precise for reliable determinations on body fluids other than serum. Clinically or chemically proved cases of magnesium deficiency are rare, but occasional instances are seen of clinical magnesium deficiency presenting as neuromuscular irritability, disorientation, fibrillary twitchings, tremor and even convulsions, which respond to magnesium therapy. If these clinical signs appear following long periods of parenteral maintenance and are associated with blood levels below the normal range of 1.5 to 2.5 mEq. per liter, parenteral administration of magnesium ion is indicated.

Disturbances of Acid-Base Equilibrium. Clinical disturbances of acid-base balance may be of either metabolic or respiratory type. Whereas, in the past, metabolic disturbances were considered to be vastly more frequent, the recent growth of thoracic surgery and the more intensive study of inhalation anesthesia have served to emphasize the comparative frequency with which respiratory disturbances of acid-base regulation actually occur in surgical patients. Consequently, it is of great importance that in evaluating cases of acidosis or alkalosis the necessary data be available to demonstrate clearly what the underlying basis for the

The use of body weight in assessing fluid balance is, of course, based on the assumption that significant changes over short periods are largely the result of changes in hydration. This assumption is true, but, of course, is not valid over periods of many days in chronically ill patients in whom cumulative decrements in tissue mass are occurring. Furthermore, it should be kept in mind that large amounts of fluid may be sequestered temporarily in areas of the body which play no role in the maintenance of circulation or the state of hydration. This so-called third space effect occurs to some extent following any operation or injury but assumes significant proportions where there are extensive areas of tissue damage or localized edema peripheral to sites of venous or lymphatic obstruction or in intestinal ileus. It would be absurd, for example, to calculate the fluid requirements for a patient with a major burn on the basis of the changes in body weight, when his fluid losses are almost entirely within his own body.

Large amounts of sodium chloride are not required for maintenance of patients who do not suffer from external losses. The normal kidney can restrict sodium excretion to much less than that contained in 1 gm of sodium chloride (17 mEq.) and the insensible water loss excluding palpable sweat contains only traces of sodium salt. This ability

of the kidney to conserve in the absence of intake does not hold for potassium ion, since 30 to 40 mEq. of potassium may be excreted by patients receiving none by oral or parenteral route. It is necessary, therefore, to include in a parenteral regimen at least 2 to 3 gm. of a salt such as potassium chloride for routine maintenance. This, however, should not be given immediately after surgery or until normal renal function has been adequately established. The losses of potassium may, of course, be much greater following the stress of major surgery, burns and trauma. In addition to the basal amounts of fluid to provide for urine output and to replace insensible losses, parenteral administration must include volume-for-volume replacement of water lost through the abnormal routes of tubes and fistulae. The replacement of solutes lost through these channels must take into account the origin of the secretions, for the ratio of sodium to chloride in various gastrointestinal fluids differs greatly from that of plasma. Their loss will produce not only over-all electrolyte depletion but also profound disturbances in acid-base equilibrium. Thus, withdrawal of normal gastric juice which contains more chloride than plasma and very little sodium rapidly produces alkalosis. Conversely, pancreatic juice which possesses a sodium concentration comparable to that of plasma but relatively little chloride causes acidosis.

was originally described by Darrow as a complication of infantile diarrhea, it is now seen at least as frequently in association with high intestinal obstruction and particularly in patients who have had prolonged parenteral maintenance without adequate amounts of potassium ion (Fig. 4). The increased extracellular bicarbonate under these circumstances is related to the high intracellular sodium which results from the movement of the latter ion into the cell as a mechanism for replacing the lost intracellular cation. A persistent hypochloremic alkalosis which is typical of the situation can be reversed only by the administration of potassium ion. The diagnosis is usually made merely by the presence of so-called refractory alkalosis. Serum levels of potassium are usually low, although they need not always be. The characteristic electrocardiographic findings—prolongation of the Q-T interval, depression of the RS-T segment and eventually inverted T waves—are valuable confirmatory signs.

The nature of the physiologic state which

follows surgery and the stress associated with serious surgical diseases explain the frequency of potassium deficiency as a surgical complication. Reference to Table 1 will indicate the amounts of potassium in milliequivalents per liter of drainage that may be lost from the body through gastrointestinal siphonage. Even when gastrointestinal siphonage is employed, however, the loss through the gastrointestinal tract is usually not the largest source of negative potassium balance, for even under normal circumstances an individual receiving no potassium by mouth may put out large amounts of urinary potassium and under circumstances of stress, imposed by a major surgical procedure or acute intestinal obstruction, these urinary losses may be greatly increased.

Although in discussing mechanisms we tend to distinguish metabolic alkalosis resulting from gastric chloride loss from that associated with the chronic depletion of intracellular potassium, these two conditions are peculiarly interrelated and in surgical patients probably never exist as separate entities. Not only does high intestinal obstruction result in depletion of potassium stores through vomitus or aspiration, representing a serious form of stress which results in potassium loss in the urine, but alkalosis itself causes depletion of intracellular potassium and excretion of this ion in the urine. In such circumstances, metabolic alkalosis is almost always accompanied by an acid urine, the so-called paradoxical aciduria of metabolic alkalosis. This apparently results from avid retention of sodium bicarbonate by the kidney, a phenomenon which is characteristic of potassium deficiency and mineralocorticoid activity on the part of the adrenal gland.

Thus, the kidney plays no role in compensation for this abnormality of acid-base balance and only potentiates the defect through the retention of sodium and bicarbonate. A three-cornered self-perpetuating cycle involving alkalosis, endocrine activity and potassium loss becomes established which can only be interrupted by the administration of potassium ion. The extent of depletion of body potassium reservoirs may be relatively small or very great and is not readily measurable by the usual criteria of plasma levels or electrocardiogram. Chloride deficit is also large and, with bicarbonate retention, chloride losses in the urine persist despite continued depletion through vomiting or aspiration. Since some loss of sodium

Figure 4. Hypochloremic alkalosis resulting from potassium deficiency in a patient following prolonged parenteral therapy without potassium replacement

clinical disturbance in pH is. In most institutions, a measurement approximating the plasma bicarbonate, such as the carbon dioxide combining power, is used for clinical purposes. Reliance on this value alone is frequently adequate if it is kept in mind that this quantity is by itself no index of the direction of the pH change. It will be recalled in this connection that the pH maintained by the buffering system of the plasma is related to the bicarbonate of the blood and the dissolved carbon dioxide, or carbonic acid, by the familiar Henderson-Hasselbalch equation:

$$\text{pH} = \text{pK} + \log \frac{\text{BHCO}_3}{\text{H}_2\text{CO}_3}$$

The bicarbonate of the plasma can be altered by changes in its rate of renal excretion and the carbonic acid concentration depends on the rate at which carbon dioxide is removed by the lungs. By their individual control of these two quantities, the lungs and kidneys are the organs primarily responsible for the preservation of normal pH in the face of circumstances tending to disturb it. In deviations of a primary metabolic nature, the initial effect is on the bicarbonate which is decreased in acidosis and increased in alkalosis. The respiratory apparatus responds to shift the carbonic acid in the same direction so that the ratio $\frac{\text{BHCO}_3}{\text{H}_2\text{CO}_3}$ which is

normally 20:1 is minimally altered. Respiration is, therefore, accelerated in acidosis and depressed in alkalosis although the latter adjustment is minimal and usually not clinically apparent. In disturbances of a primary respiratory nature, however, the initial effect involves the carbonic acid. Compensations must be made by the kidneys which retain or excrete bicarbonate. They retain bicarbonate when carbonic acid has been inadequately removed by the lungs and they excrete an excess of bicarbonate to compensate for the alkalosis which follows hyperventilation. Therefore, since the final bicarbonate value, which is the most commonly used index for acid-base disturbances, is elevated in metabolic alkalosis and respiratory alkalosis and depressed in respiratory acidosis and metabolic acidosis, it is obviously not possible to distinguish between acidosis and alkalosis on the basis of the carbon dioxide combining power alone. In most instances, the clinical information points to a disturbance which is primarily of metabolic or of respiratory origin. Occasionally, however, the situation is not clinically

Figure 3 Hypochloremic alkalosis. Effect of several days of nasal tube suction, without adequate chloride replacement, on the composition of the plasma. Note reduction of chloride with expansion of bicarbonate and essentially normal sodium.

cally obvious and the complete acid-base picture must be obtained by establishing a value of a second of the three possible variables in the Henderson-Hasselbalch equation. This is done ordinarily by determination of the blood pH and preferably with the simultaneous measurement of the total carbon dioxide content of the arterial blood.

Metabolic alkalosis is most commonly seen in surgical patients as a result of the loss of large amounts of gastric secretion, a material which has high chloride content with relatively low concentrations of sodium. It is ordinarily lost either through vomiting or continuous inlying gastric suction. Alkalosis can develop in as brief a time as twenty-four hours in the face of total diversion of gastric content. Figure 3 illustrates the ionic pattern in such a case compared with the normal concentration. As was mentioned above, this simple situation can be corrected by administration of chloride ion in the form of sodium chloride, and acid salts are rarely indicated.

A more complicated situation leading to metabolic alkalosis is that associated with potassium deficiency. It is most frequently recognized under circumstances in which repeated administration of sodium chloride or even ammonium chloride results in no alleviation of metabolic alkalosis. Though it

sunken eyes and dryness of the mucous membranes. Change in body weight is the best index of the development of dehydration. Serum electrolyte concentrations can be elevated, depressed or normal and therefore give no indication of the over-all deficit of ionic components. If a patient admitted to the hospital has been vomiting or has suffered other perceptible fluid losses, it must be remembered that if he has not been drinking, water loss almost invariably exceeds electrolyte loss so that it is best to begin hydration with solutions which are dilute with respect to ionic constituents. Subsequent blood chemical determinations frequently reveal the presence of electrolyte deficit as a more normal state of hydration is approached.

Edema in association with surgery was frequently seen in earlier days when "physiologic saline" was used routinely as a hydrating solution. After the recognition by Collier and his associates of the tendency for patients to retain sodium in the period after surgery, excessive use of sodium chloride was almost universally discontinued. Post-operative edema became far less common. In this situation, as with dehydration, the serum levels of ions do not, of course, give any index of the over-all excess of extracellular electrolytes which may be present. The familiar clinical signs of pulmonary and peripheral edema are obviously of the greatest importance and serial body weight determinations will demonstrate incipient fluid retention long before clinical edema is apparent.

Disturbances of Concentration. Reference has already been made to the importance of the sodium concentration of the extracellular fluid and its critical role in the distribution of water between the cells and the fluid which surrounds them. Because of the importance of this concentration, it is not surprising that the normal sodium level is maintained within rather narrow limits. Nevertheless, following surgery and in the absence of oral intake, elimination of the factor of thirst and with certain impairments in renal function, disturbances in the regulation of sodium concentration do occur. As has already been pointed out, such a deviation represents in effect an abnormality in the over-all effective osmotic properties of extracellular fluid.

It was stated above that, following major operations, the sodium concentration of the plasma tends to drop despite the fact that sodium balance inclines to be positive. This

situation results from an intolerance of the postoperative patient to administered water with subsequent dilution and possibly also from factors having to do with translocation of the sodium ion possibly into other reservoirs which are at present poorly understood. Although this frequent depression of sodium concentration is not ordinarily accompanied by symptoms, it occasionally is severe enough to cause profound functional disturbances. The most dramatic of these involve the central nervous system which reflects the depression of sodium concentration and reacts to intracellular shift of water by the physical signs of stupor, irrationality, neuromuscular phenomena and sometimes convulsions. Depending on the circumstances leading to such clinical symptoms, they are referred to as "water intoxication" or "low sodium syndrome." The most profound effects are produced when an injudicious amount of water is given to a patient within the first two to three days after surgery. Nevertheless, cases of so-called water intoxication have been observed under circumstances in which entirely appropriate amounts of water have been administered (Fig. 6). The low sodium syndrome has been particularly observed following the operation of valvuloplasty for mitral stenosis. The cardiac impairment in these individuals prior to surgery creates an even greater intolerance to administered water than the usual surgical patient exhibits. It is of great interest that the total measurable sodium in such patients actually tends to be high as does their total extracellular space. This further emphasizes the fact that it is the concentration of the sodium in the plasma which is of the greatest importance in regard to the cellular content of water.

Most patients with mitral stenosis have, of course, been prepared for surgery with low sodium diets and mercurial diuretics. Nevertheless, it does appear that they have an even greater susceptibility to postsurgical complications of dilution and hyponatremia than other patients so prepared. They behave as though under an extremely potent antidiuretic stimulus and the reason for this is not entirely clear. With low sodium levels, antidiuresis should be inhibited. However, there is a great deal of evidence that the antidiuretic response is sensitive to volume as well as osmolar stimuli and there is some evidence to indicate that the volume receptors for posterior pituitary antidiuresis are located in the region of the left atrium or pulmonary veins. It is tempting to suppose

has also occurred through gastrointestinal routes, it is frequently justifiable to initiate therapy with a combination of sodium chloride, potassium chloride and ammonium chloride with subsequent adjustment in the proportions of these components as dictated by the changes in plasma electrolyte levels.

Acidosis of metabolic origin is frequently seen following the loss from the body of secretions possessing high sodium concentration. The typical case is that of pancreatic fistula. Pancreatic juice which possesses a sodium concentration comparable to that of plasma but very little chloride is almost an isotonic solution of sodium bicarbonate. Diversion of this solution from a normal path of being secreted and reabsorbed from the intestine results very rapidly in profound acidosis with a blood picture of low sodium and low bicarbonate values. The electrolyte picture resulting from a chronic pancreatic fistula is illustrated in Figure 5. A similar situation is, of course, produced by sodium loss through fistulae from the lower intestine where the sodium-to-chloride ratio is also high. Reversal of the blood electrolyte picture in these situations cannot be ordinarily accomplished with sodium chloride, and the use of sodium solutions with labile or metabolizable anions, such as sodium lactate or sodium bicarbonate, is ordinarily required.

The examples of acidosis just described result from the loss of the extracellular cation or what was referred to in the older clinical terminology as "fixed base." Another type is the result not of loss of base but of accumulation of abnormal acids which results in displacement of bicarbonate. An example of this is the acidosis which accompanies uremia with accumulation of phosphate, sulfate and organic acids. Another is the picture which results from the excessive reabsorption of chloride from the intestine following surgical procedures in which the ureters are transplanted into the intestinal tract. This so-called chloride acidosis frequently follows such procedures but is more likely to exist when drainage of the intestinal segment is inadequate or when poor renal function exists in addition to discharge of urine into the intestine.

Respiratory acidosis associated with anesthesia and thoracic surgery has become a matter of increasing significance in recent years. It is important to recognize that the administration of oxygen to individuals with respiratory impairment resulting from pulmonary disease or inadequate pulmonary tissue or impairment of motor respiratory

Figure 5 Hyponatremic acidosis. The result of chronic sodium loss through a pancreatic fistula. Note reduction of sodium with corresponding contraction of bicarbonate. Cross-hatch indicates normal values assumed (cations) or determined by subtraction (anions).

activity will maintain oxygen saturation of the blood but may not achieve adequate removal of carbon dioxide. The consequences of respiratory acidosis in the genesis of cardiac arrhythmia and cardiac arrest are profound.

Disturbances of Fluid Volume. A consideration of daily importance in the management of postoperative patients is the maintenance of normal extracellular fluid volume. This quantity, which is very sensitively regulated in the normal individual, is readily subject to distortion when the oral intake, or the effect of thirst, is removed and when renal regulations of fluid volume may be impaired. Dehydration in the strict sense refers to the effects on the body of water loss alone. It most frequently is used, however, to describe the deficiency of water in combination with electrolytes. Pure water dehydration is actually rare. The familiar signs of combined extracellular fluid deficiency include loss of turgor of the skin,

Ischemia resulting in varying degrees of necrosis of renal cells is histologically most frequently demonstrable in the distal tubular epithelium. It is not at all clear, however, that those cells which can be seen to be damaged under a microscope are the only ones which are functionally impaired. The important fact is that if one follows the changes in the damaged tubular epithelium, regeneration begins to occur between eight to fourteen days and, if the patients can be maintained in adequate fluid and metabolic equilibrium until that time, the majority can survive such periods of severe reduction in renal function. In the older literature, many instances of survival from periods of prolonged anuria were recorded with little specific therapy. Unfortunately, when the use of parenteral fluids and electrolytes became widespread, the overzealous use of these agents resulted in the death of many such patients. In recent years, a number of methods of artificial dialysis, the most successful being the Kolff artificial kidney, have come into use. Although these have a definite field of usefulness, the mainstay of treatment in the majority of patients with acute renal insufficiency is cautious and quantitative fluid management.

Anuria is arbitrarily defined as a urine output of less than 100 cc. in twenty-four hour periods. Characteristically, anuric patients have certain electrolyte deviations. In cases as they are ordinarily seen, both sodium and chloride in the extracellular fluid tend to be low (Fig. 7). The main reason for this is that no matter how early the condition is recognized the patient will have been given, or have ingested, water which has not been excreted. Consequently, a certain amount of overhydration exists from the start. In chronic renal insufficiency, the inability of the kidney to conserve sodium may play a role in the genesis of this diluted picture but is obviously of no importance in the completely anuric individual. In addition to the alterations in sodium and chloride, bicarbonate is almost uniformly reduced. This indicates metabolic acidosis resulting from a combination of the depressed serum sodium level and an abnormal accumulation of anionic metabolites such as sulfate, phosphate and organic acids.

Fluid administration must be limited to that which is required to replace insensible losses. In addition to accurate recording of intake and output, daily determination of the body weight is absolutely necessary because of the great variation in insensible

water loss among individuals. It will be found by such measurements that most of these patients should be given only from 500 to 750 cc. of fluid daily to replace their water loss, and sometimes as little as 300 to 400 cc. Very rarely is more than 1000 cc. required. If suction tubes or fistulae are present, the loss through these channels must be added to the above. Within reason, it appears definitely valuable to take what measures are necessary to maintain as normal as possible a composition of the extracellular fluid. This should be done only when it is possible to add the necessary components without exceeding the rigid quota of fluid established by the insensible water loss. Therefore, particularly when the sodium level is low, it is advantageous to use small amounts of sodium bicarbonate or sodium lactate to correct the metabolic acidosis. Similarly, when sodium and chloride deficiencies clearly exist and are not the result of overhydration, appropriate amounts of these ions should be given. Frequently this must be done by resorting to hypertonic solutions in order not to increase overall fluid intake. The only deviation which cannot be dealt with in this manner is a

Figure 7 Effect on serum electrolytes of acute

Figure 6 Water intoxication occurring thirty hours after operation (colectomy) in an elderly woman with cardiac disease who had been maintained on a low sodium regimen prior to surgery

that the posterior pituitary has become adapted to a barrage of inhibitory stimuli from a distended left atrium and that the release of left atrial pressure is followed by secretion of an extraordinary amount of anti-diuretic material. This, of course, is conjecture awaiting adequate experimental investigation. The practical fact is that the intolerance of these individuals to even slight excesses of water be recognized and fluid administration during and after surgery rigorously limited.

Of considerable theoretical interest and occasional practical importance is the clinical effect which results when the serum sodium is forced above its normal level. This situation is fortunately rare since the normal mechanisms for regulation of the extracellular fluid concentration rather strongly resist any elevation of the serum sodium. There are surgical situations, however, wherein such hypernatremia may occasionally be observed. One is in certain types of central nervous system damage, namely, those involving hypothalamus and the frontal lobes. The second follows certain types of damage

to the kidneys. Although the latter was originally described in connection with sulfathiazole poisoning, it is now recognized that it can follow almost any type of acute renal damage and, as more cases are studied, it would appear that transient hypernatremia of mild degree is a rather common part of the sequence of recovery from acute renal injury. An important factor underlying the development of hypernatremia in the phase of diuresis may be the excretion of a large load of crystalloid materials, such as urea, which act as osmotic diuretics. The underlying mechanism responsible for clinical signs of hypernatremia and hyperosmolality is clearly a movement of water from the intracellular to the extracellular compartment in response to the elevation of the serum sodium. Here again, the cells of the central nervous system are particularly sensitive and the signs which result are those of profound stupor, central nervous system depression, hyperpyrexia and, occasionally, athetoid and choreiform movements of the extremities. Although little is known of the treatment of this disorder, it is apparent that, whenever feasible, complete avoidance of parenteral salt administration must be enforced with administrations of as large amounts of salt-free glucose solution as the patient can tolerate.

Management of Acute Renal Insufficiency. Acute renal shutdown, being a rather common complication of surgery, is one that every surgeon must be prepared to meet. The exacting nature of this problem reminds one that in most situations gross discrepancies from the ideal fluid and electrolyte management are compensated for by the kidney whose regulatory powers are normally able to correct the errors of the clinician. In the absence of renal function, however, fluid therapy must be extraordinarily precise for every measure that is taken is reflected in the actual composition of the interior of the body.

Although the reactions caused by incompatible transfusion and prolonged periods of shock appear to be the cause of many cases of postsurgical or post-traumatic anuria, it must be admitted that many instances of such acute renal failure are ascribable to no single cause. It would appear, however, that in renal shutdown which does not result clearly from transfusion reactions, or other toxic agents, the common factor is reduction of effective blood supply to the kidney. This may occur even when reduction of the systemic blood pressure does not take place.

mounting potassium level, an unfortunate but frequent complication of prolonged anuria. Within limits, this can be prevented by the avoidance of oral and parenteral administration of potassium ion and omitting blood transfusions when they are not absolutely necessary.

Since reduction of extracellular pH favors movement of potassium out of the cell, it is important to treat acidosis when possible by administration of sodium bicarbonate or lactate. Although this may require use of hypertonic solutions, and occasionally the administration of more sodium ion than would otherwise be desirable, reduction of extracellular potassium to below critical levels can frequently be effected. The use of appropriate exchange resins is also of value and recent experience suggests that the most successful form of administration is by enema, the resin being suspended in 5 per cent glucose solution. Very transitory reduction in serum potassium level can be achieved by giving glucose intravenously with or without insulin, which causes a small amount of the plasma potassium to be transferred to the interior of the cell in association with glycogen. Persistent increase in potassium level over the level of 7 mEq. per liter must be specifically dealt with and to date the only effective mechanism for doing this is perfusion with an artificial type of dialyzer.

With this type of treatment many instances of anuria will be carried to spontaneous diuresis within seven to ten days. At this point careful scrutiny of the chemical picture is also required, for all moieties of renal function do not recover simultaneously. In some instances, the initial diuresis will include large amounts of all the extracellular electrolytes and in the absence of complete tubular regeneration the urine may very closely approximate glomerular filtrate. Under the latter circumstances, very large amounts of water and electrolytes may be required to avoid the creation of overwhelming extracellular fluid deficiency or serious hyponatremia and hyponatremia. It has already been mentioned that under other circumstances, sodium and chloride may not be excreted at all in the urine, but only large amounts of water may be put out during the period of diuresis. Here, as has been mentioned, hypernatremia may develop with its attendant effects on the central nervous system. When this situation is recognized, only salt-free fluids should be given, frequently in very large amounts. It

is necessary, therefore, to follow patients carefully not only during the period of anuria but through the phase of diuresis.

because of the many regulatory functions which the adrenal steroids play in tissue metabolism. An account of endocrine changes alone brings little of usefulness to the practicing surgeon, no matter how great his interest, because it is the associated metabolic changes and their pathologic variants in his sick patients which are really of critical practical importance. Although the precise relationship between surgical endocrinology and the metabolic response is unknown at this time, the two occur together and are best described together as a basis for the understanding of normal convalescence and, through this, the abnormal.

It is our purpose to outline the underlying principles which should guide daily surgical care, according to the chronological sequence of convalescence. First are described the early changes after injury, then the period of spontaneous regrowth and, finally, certain aspects of late convalescence. A few of the major abnormalities and variations in these convalescent patterns are then discussed.

CATABOLISM: THE EARLY PERIOD OF STRESS AFTER INJURY

An intraserosus operation involving extensive dissection and anastomosis, such as gastrectomy or combined abdominoperineal resection, transperitoneal nephrectomy, colectomy, splenectomy or lobectomy, may be considered as the prototype "moderate trauma," a trauma occupying a midposition in the scale of injury to which the flesh falls heir. The subsequent description is based on such a midscale trauma as a "normal" with which other patterns of convalescence may be compared.

Endocrinology. Adrenal cortex. Endocrine changes are evident very close to the time of the incision. In occasional instances, the lowering of eosinophil count prior to surgery may be evidence of preoperative adrenocortical stimulation by apprehension or medication. Shortly after the induction of an ether anesthesia, the eosinophil count (often after a transient rise) drops to zero, or near zero, and remains there for from two to five days. Coincident with this sudden drop in eosinophil count is a rise in the free serum 17-hydroxycorticoids from normal values of 10 to 20 micrograms per 100 cc. to stimulated values in the range of 40 to 80 micrograms per 100 cc., depending on the nature of the anesthetic and the magnitude of the trauma. The fall in the eosinophil count is usually complete two or

three hours after the induction of anesthesia. The peak in serum steroid is often not reached for an additional three or four hours, characteristically in midafternoon of the day of a morning operation. These two changes are selected from amongst a host of measurable indices as indicating an increased secretion of adrenal steroids of the compound E-F group, represented largely by compound F, or hydrocortisone, in normal human adrenal secretion.

Because of this increased secretion of adrenal substances, there is an increased excretion in the urine of steroids which have largely been conjugated in the liver as glucuronides. The duration of this adrenal secretory increase varies, but normally the blood steroids have returned to normal by the next day. The eosinophil count may remain near zero for from three to five days before gradually swinging upward. The increased excretion of steroid hormones in the urine may continue for two or three days after the blood level has returned to or near normal. This suggests that adrenal secretion is still increased but that the mechanisms for clearing the blood (hepatic) and excreting the conjugates (kidney) have increased their rate so that they can keep up with the increased adrenal production.

Although many endocrine changes are involved in surgical endocrinology, more information is available on adrenal changes than any of the others. The teaching for years has been that the adrenal secretes three classes of hormones (glucocorticoids, mineralocorticoids and androgens) and that the urinary 17-ketosteroid excretion represents end products of androgen output. We now know that neither of these time-honored contentions is accurate. The adrenal secretes a variety of steroids, many of which possess in one molecule and to varying degrees several of the actions: glucose-nitrogen activity, sodium activity and sex-hormone activity, the latter being either estrogenic, androgenic or progestational. Indeed, progesterone is one of the adrenal secretory products, being an 11-17-desoxycorticoid, and most mineralocorticoids including 11-desoxycorticosterone (DOCA) have progestational activity! The steroids which terminate their life in the body with a ketone group on carbon 17 (the 17-ketosteroids) are not only those which start with this configuration, such as the testicular androgens and adrenal androgens, but also a variety of other compounds including cortisone and hydrocortisone which lose their carbon 17-side-chains in the course

ENDOCRINOLOGY AND METABOLISM IN SURGICAL CARE

By FRANCIS D. MOORE, M.D., and
RICHARD W. STEENBURG, M.D.

FRANCIS DANIELS MOORE is a Harvard College and Medical School graduate who was born in Illinois. He was trained in surgery at the Massachusetts General Hospital. He now holds the Moseley Chair of Surgery at Harvard Medical School and is the Surgeon-in-Chief of the Peter Bent Brigham Hospital. Dr. Moore represents the group of surgeons of today who have applied a basic knowledge of biochemistry and metabolism to surgical problems.

RICHARD WESLEY STEENBURG, a Nebraskan by birth, was educated at Stanford University, Harvard College and Harvard Medical School. He is now an Instructor in Surgery at the Johns Hopkins Medical School and Assistant Chief of Surgery of the Baltimore City Hospitals.

INTRODUCTION

During the past two decades, it has been possible to map out in some detail a variety of endocrine alterations with associated metabolic changes which are characteristic of surgical convalescence, just as other metabolic and endocrine sequences are characteristic of puberty, pregnancy or senility. Viewed in this light, surgical convalescence is a bodily adjustment to a new set of external and internal circumstances. The circumstances involved are those of acute disease and tissue trauma, the complex response results in healing of the wound and restoration of the individual to normal physical,

economic and emotional activity. These changes of convalescent endocrinology and metabolism are common to all fields of surgery and all areas of the human body, although the nature of the wound itself is of great importance in determining the depth and duration of the metabolic response. The metabolic changes produced by a fracture, for example, are different from those produced by a burn, even though certain of the endocrine responses have much in common. An understanding of this metabolism is the basis for effective care in surgery.

The role of the adrenal glands in general surgical physiology is an important one

unless they have been rendered euthyroid by the administration of thyroid substances. Yet there is no incontrovertible evidence that systematic alterations in thyroid function follow trauma and there is a wide variety of disease processes which increase oxygen consumption without demonstrable thyroid imbalance.

There is clinical evidence that gonadal function is decreased after injury. In the female, amenorrhea occurs after extensive trauma or surgery and there is often a male-type hair growth observed in women who have very extensive injury such as burns. That this is not solely a nutritional factor is suggested by the observation that weight loss due to other forms of disease is not necessarily associated with such reversion to a neutral sexual pattern. Reproductive activity resumes some time during or after the phase of positive nitrogen balance.

Systematic changes in the function of the pancreatic islets and the parathyroids have not been observed after trauma. The mobilization of liver glycogen and formation of glucose from protein result in an elevated blood glucose after injury, effects hastened by adrenal medullary and adrenal cortical activity. When immobilization is prolonged, there is a marked loss of body calcium.

The Wound. During the early period of post-injury metabolism, the primarily sutured wound has little tensile strength. The accumulation of leukocytes and of extracellular fluid containing the compounds found in plasma (many of which are mobilized from muscle) characterizes this period. If dead tissue and virulent organisms do not abound, the wound then commences to gain tensile strength by the conversion of protein precursors into the intercellular structure of collagen. Vitamin C is a requisite for this reaction to occur.

Metabolism. Protein and nitrogen. Protein metabolism is profoundly affected by trauma. Observations of this phenomenon formed the earliest metabolic studies of trauma and there is a wealth of information available in the literature. The characteristic change consists of an increased absolute urinary nitrogen excretion rate despite diminished intake, with negative balance as a result.

The normal adult male ingests approximately 10 to 12 gm. of nitrogen a day and excretes a like amount, all but 1 gm. of which is excreted in the urine. He is, therefore, referred to as in zero balance of nitrogen. After injury, even though the nitrogen

intake may fall to zero, as it so characteristically does, the excretion is increased and, after major injury, nitrogen excretion rates in the urine of 12 to 15 gm. a day are regularly observed. After more extensive injury, the urinary nitrogen loss may range as high as 25 gm. per day. This amount of nitrogen (20 gm.) lost daily over a period of four days represents the catabolism of about 500 gm. of protein—an extreme figure but not an unusual one. This much protein would form the cellular mass of approximately 2000 gm. of wet lean tissue such as muscle. This large amount of tissue which is catabolized after major injury is mentioned to emphasize that there can be little mystery about its source. Except in most remarkable circumstances, the wound itself is a source of only a small fraction of this nitrogen. Changes in size of the liver, heart, lungs, kidney or other viscera would have to be massive, of the order of magnitude of 50 per cent reduction in size, in order to account for even a fraction of this nitrogen. It is well known that these organs do not diminish in size after trauma; indeed they are apt to increase. This leaves the skeletal muscle, which forms the great mass of protein solids in the body composition, as the source of the nitrogen lost after trauma. After major injury, the patient feels weak and if his injury has been considerable, as in a burn or in a war wound, he is extremely weak for two or three weeks after the injury. This weakness is correlated with a visible and easily measurable reduction in size of major muscle masses. It is apparent, therefore, that trauma excites the mobilization of small-molecular-weight nitrogen compounds from the protein of muscle, by an intense catabolic destruction. These nitrogen compounds are excreted in the urine, most of them having been converted into urea en route from muscle to urine. There are interesting and important changes in excretion of certain other small nitrogen compounds such as the amino acids, but these are of quantitative minor import though of great significance in providing raw material for wound synthesis.

Potassium. A number of electrolytes exist in the cell with protein and the whole is bathed in an amount of water which comprises approximately 73 per cent of the weight of the cellular mass. The intracellular electrolytes are chiefly potassium, phosphate, sulfate, calcium and magnesium and of these substances, the most information is available with respect to potassium. After a

of metabolism and have it replaced by a keto group, probably in the liver. The adrenal hormones are interconverted, inactivated by conjugation or reduction, oxidized and excreted at varying rates, depending upon secretion, liver function and kidney function. Given a constant rate of secretion, sudden changes in inactivation rate could give the appearance of enhanced activity—and precisely this appears to happen at least to some extent after surgical trauma, in the course of which liver function is almost always impaired.

For these reasons, one must view the measurements in blood or urine of a certain steroidal configuration as indicating crudely only a small fraction of the net result of a very complex endocrine change involving secretion, degradation, interconversion and conjugation. The occurrence of such sudden and massive changes in the 17-hydroxycorticoid fraction leaves little doubt that the smooth tenor of adrenal function is drastically altered by tissue trauma.

The secretory impulse which follows surgery appears to involve hydrocortisone predominantly, the concentration of this hormone being much larger than any of the others. The increased concentration of this substance in blood and urine may be measured by a colorimetric method specific for corticoids with a hydroxyl group on carbon 17 (compounds E, F and S). It is such measurements which have been referred to in the foregoing account of postoperative changes.

Mineral activity is not prominent in hydrocortisone, though present. An extremely potent electrolyte-active steroid, aldosterone, is normally secreted by the adrenal independent to some degree of ACTH changes. The increased tendency to retain salt after surgery suggests an increased secretion of this substance. Thus has not as yet been established and again we must recall that changes in inactivation or excretion could alter the peripheral metabolism, as well as changes in production.

The pituitary and hypothalamus are the keystones of this endocrine response, since it is through these agencies that the trauma initiates the endocrine response. The initial change is an increased secretion of ACTH by the pituitary, evidently in response to stimuli originating in the periphery and mediated through the hypothalamus.

Adrenal medulla. Coincident with these measures of increased adrenal cortical activity after trauma are evidences of activity

of other endocrine glands. Increased pulse rate and narrowing of pulse pressure with increased sweating and decreased capillary circulation in the skin are evidences of adrenal medullary activity. These signs are most marked if the patient is in severe pain, is very apprehensive or approaches clinical shock due to reduced blood volume. In the absence of any of these circumstances, the adrenal medullary evidences may be quite minimal except for the effects of ether anesthesia which evidently are associated with a very marked production of epinephrine and related compounds by the adrenal medulla.

Antidiuresis. A normal individual given an intravenous injection of a 5 per cent solution of glucose in water rapidly increases his urine flow from normal rates of 1 ml. per minute to rates as high as 6 to 8 ml. per minute. Coincident with this, there is a drop in the urine osmolarity from normal values of 500 to 800 milliosmols per liter down to values nearer 200 milliosmols per liter. By dint of this water diuresis, the solute concentration of serum (as measured by sodium, protein or total osmolarity) undergoes no lasting change. This is a normal diuresis in response to water infusion. After surgery, even of rather minor extent, this normal diuresis of a water load is markedly or completely inhibited. The same infusion given under these circumstances produces virtually no increase in urine volume or decrease in urine osmolarity. The water is retained with a resultant fall of serum osmolarity, from normal values of 280 to 290 milliosmols per liter down to values around 260.

These are the observations in surgical patients which have demonstrated the occurrence of "postoperative antidiuresis." This is clearly of importance in surgical care and it appears to be another evidence of endocrine activity after trauma. Presumably, this effect is produced by stimulation of the posterior pituitary gland to elaborate its antidiuretic hormone. Although this has not been proved, several workers have measured an increase in the urinary excretion of antidiuretic substances in surgical patients.

Other endocrines. After trauma there is an increase in oxygen utilization and an evident increase in the rate of oxidation of tissue substrates, particularly fat and protein. This might appear to be thyroidal in origin. It is certain that a normal thyroid is essential for a normal trauma response, patients with hypothyroidism are notoriously intolerant to surgical trauma and medication.

zero for the obvious reason that the patient will not, cannot or should not eat. The glucose administered intravenously provides a small supply of readily available calories which may be the only calories supplied until oral intake again begins. During the first five days after trauma, there is little to suggest that forcing further calories affects the patient favorably. This is in sharp contrast to the situation later on in convalescence when the administration of exogenous calories is of vital importance for recovery.

The blood sugar quite regularly rises after trauma and there is some tendency for glycosuria and decreased glucose tolerance. This "anti-insulin effect" may be due to the increased amount of steroid circulating in the blood, to the mobilization of liver glycogen or to the sudden production of carbohydrate by the degradation of fat or protein.

Serum protein. During this early phase after trauma, the serum protein concentration does not change markedly. If there is acute dehydration due to loss of water or water with salt, the serum protein may rise along with the hematocrit reading. If there is accumulation of water and salt due to overadministration of these substances, the serum protein will fall. Such excesses of water and salt are the commonest causes of hypoproteinemia in surgical patients.

Clinical Management. After moderate trauma in well nourished individuals, the metabolic management of this phase of convalescence presents few problems.

The most important therapeutic step is that of a well performed operation, accurately directed to the major disease from which the patient suffers and carried out in such a way as to impose on the wound a minimum load of contaminated and dead tissue and to avoid hypotension, oliguria, distention or extrarenal loss. All of these distort the normal convalescent sequence and divert the resources of the organism.

If the patient's oral intake is interrupted for only one day, he will get along well without any intravenous or other parenteral therapy. If more extensive trauma has occurred, the administration of intravenous fluids for a day or two may forestall dehydration and provide water until intake starts. The administration of 50 to 150 gm. of carbohydrate by vein in these first few days forms an inevitable accompaniment of water administration and provides a small caloric ration. Enough water should be administered to cover the losses from the body by lungs, skin and urine, allowing for urine

output of between 350 and 750 cc. on the first day and somewhat more on subsequent days.

When there are no extrarenal losses of water and electrolyte, the administration of electrolyte is usually unnecessary during the few days before oral diet is recommended. Small amounts of electrolyte do no harm, however, and many prefer to give enough to allow for small losses. As an example, if enough potassium, sodium and chloride are given to allow for 40 mEq. of each in the urine during the early postoperative days, this purpose will be accomplished without excess. Under no circumstances should the patient be given excesses of electrolyte or of water since in either case retention will result, with the production of serum dilution or hypoproteinemia or both. Furthermore, quantitative replacement of all urinary losses of sodium and chloride should not be attempted.

When trauma has been extensive, and is accompanied by sepsis, continued interruption of oral intake, high fever, continuing blood loss, wound edema, extrarenal loss or renal disease, the management of this phase of convalescence requires extremely accurate and considerably more complex therapy. The principles involved are based firmly on the endocrine and metabolic facts mentioned above for normal convalescence. The administration of fluids, electrolyte or blood should be carefully balanced to equal the loss, recalling that renal excretory patterns are keyed to conservation of extracellular water and salt. When the interruption of oral intake can be expected to last for more than three days, it is advisable to commence potassium administration by vein on the day of, or the day following, surgery, using 40 mEq per day as a general rule to cover renal losses and larger amounts when extrarenal loss is prominent.

ANABOLISM: THE PERIOD OF REGROWTH

Endocrinology. As mentioned previously, the initial burst of adrenal steroid activity which follows trauma is rather short lived, at least as judged by the increase in serum and urine steroid concentration. The eosinophil count rapidly returns to normal, often reaching values considerably higher than those observed preoperatively. It should return to normal by the fifth day after mild trauma. Evidences of a posterior pituitary-like effect in the stress phase immediately after injury were found in the tendency to

surgical operation, potassium excretion is increased in the urine. The normal adult consumes about 100 mEq. of potassium each day and excretes a like amount in the urine. If his intake is suddenly stopped, he excretes about 40 or 50 mEq. in the urine the first day and then over a period of days, or weeks, his urinary potassium excretion is gradually reduced to a minimum figure of about 10 mEq. per day. After major surgery—with no potassium intake—the urinary excretion ranges from 70 to 100 mEq. the first day and for the next two or three days the potassium excretion continues to be greater than one would expect in starvation alone. The amount of potassium lost from the body in the first four days is from 150 to 300 mEq. as an average. For the most part, this potassium may be considered as coming out of cells along with nitrogen, as the cellular structure is destroyed or atrophied following trauma. In most instances, however, there is some "excess" potassium excreted above that which would be expected to come out with the nitrogen alone. Potassium and nitrogen exist in muscle in a fairly fixed ratio at 2.7 to 3.0 mEq. potassium per gram of nitrogen. After injury, the potassium is lost at a rather higher potassium-nitrogen ratio and by the same token it starts to return to the cell somewhat sooner than nitrogen. This "excess" potassium is presumably removed from the cell in exchange for hydrogen or sodium ions, or both, and this abnormal state of affairs reverts to normal more rapidly than the resumption of true tissue anabolism. After this initial potassium loss, the body rapidly regains potassium as feeding is resumed.

Sodium, chloride. Both sodium and chloride are conserved during the early phase after surgery. As a general rule, more sodium is retained than chloride. In terms of renal excretion the sodium conservation mechanism operates more actively than that for chloride. On the day of operation, sodium excretion may continue, but at a reduced rate with amounts from 10 to 50 mEq. being lost in the urine, if no sodium is given. Then, in the next two or three days, sodium conservation becomes evident and the sodium excretion in the urine is reduced sharply to from 1 to 10 mEq. In more severe injury, particularly when there is an oligemic phase, the reduction in sodium excretion may commence immediately. If sodium is given intravenously during this phase, there is an increase in sodium excretion over that observed when no sodium is

given. The sodium excretion will not keep pace with the infusion, however, and a strongly positive sodium balance will result. The duration of this sodium conservation phase is among the most variable features of post-traumatic metabolism. Usually, in well nourished individuals who have had a major injury or are undergoing surgery, sodium conservation starts rapidly and passes off in three or four days with fairly clear-cut sodium diuresis, during which sodium excretion is increased. In individuals who are less well nourished, sodium conservation may be a little slower to start but persists for a much longer time and diuresis may never be clear cut.

Serum electrolytes. Early after trauma and coincident with these changes in metabolism is a tendency for the serum sodium concentration to fall (to 130 to 135 mEq. per liter) and the potassium concentration to rise (to 4.8 to 5.3 mEq. per liter). These tendencies appear to be paradoxical in view of the opposite nature of the concomitant balance changes. The explanation of the concentration changes is unknown and in normal circumstances it is of no more than passing interest clinically, but in the presence of depletion, shock or heart disease these changes may become tremendously exaggerated and be a threat to survival.

Body weight. Body weight tends to fall sharply after trauma, particularly if the trauma is in a previously well nourished patient, and if there is not a large area of edema accumulation, as in a burn or a crush. If traumatic edema accumulates, the weight loss may be obliterated or replaced by a gain because of the accumulation of water and salt. When this fluid is subsequently excreted, the patient's weight will fall sharply down to the level which would have been attained had catabolism of fat and lean tissue been the only occurrences. Following moderately severe trauma in well nourished people, one may expect a loss of approximately 3 kg. of weight in the first five days. In more extensive injury, the loss may be two or three times as fast. This lost tissue is about one-half fat (the increased oxidation of which is one of the characteristic changes of convalescence) and one-half lean tissue (muscle) which is the source of nitrogen in the urine as already mentioned. This weight loss rate is gradually reduced, reaching a plateau, and later giving way to the weight gain of convalescent anabolism.

Calories, glucose. The caloric intake immediately after trauma is usually reduced to

of nitrogen metabolism is the positive balance of later convalescence. While we may view the initial nitrogen loss with some tolerance, not knowing of any deleterious results, we may take no such relaxed view toward failure in subsequent anabolism. Nitrogen gain and protein synthesis are absolutely essential for recovery. Without them the patient cannot return to a position of social usefulness, reproductive activity or the enjoyment of life. He will heal his wound—but there his achievements will cease.

As to the relation of nitrogen balance to wound healing, one commonly hears the statement that wounds will not heal unless the patient goes into positive nitrogen balance. This is not the case. Most wounds heal readily during a negative nitrogen balance and it is commonplace after very extensive injury, or surgery, for the wound to heal to a state of tensile strength which permits removal of the sutures and the resumption of function of the intestinal tract, for instance, while the patient is still in negative nitrogen balance. This is not a rarity; it is a daily occurrence. It has been hypothesized that the mobilization of nitrogen from body stores has as one of its natural purposes the provision of small-molecular-weight nitrogen compounds as building blocks to provide the tissue which heals the wound. Such a view is merely an interpretation of natural events, but it is based on the fact that patients accomplish the initial phases of wound healing during the negative-nitrogen phase. The most egregious failure of wound healing (manifested by wound dehiscence and the complete failure of fibrosis to occur) is not associated with an unusual degree of nitrogen loss. Indeed, it is somewhat commoner in depleted individuals with cancer in whom the post-traumatic mobilization of endogenous nitrogen is halting or scanty. And finally, as mentioned above, the later assumption of nitrogen anabolism achieves its importance not because of wound healing but because it permits the regrowth of muscle and resumption of normal bodily strength, vigor and visceral function.

Potassium balance becomes positive during this anabolic period and potassium loading starts significantly prior to positive nitrogen balance in most instances as described above. It remains slightly positive throughout the phase of spontaneous anabolism.

Weight loss slows down as the metabolic corner is rounded. If adequate diet cannot

begin, it persists at a slower rate. As diet begins, a slow upward trend commences.

Clinical Management. If the patient will eat his food normally, the clinical management of this phase of convalescence poses no therapeutic problem. Recognition of the underlying requirements for exogenous calories, and of the calorie-nitrogen ratios required, forms the basis for the rational treatment of surgical convalescence. As mentioned above, the provision of large caloric intakes is of dubious benefit in the early period of catabolism. If food given by mouth is not absorbed or is vomited, the attempt to provide food early may actually be very harmful. There is no greater tragedy than distention or aspiration as a complication of unnecessary early diet forcing. The nutritional objective in the early period is a scaphoid abdomen.

As anabolism is achieved, peristalsis is resumed, there is anal excretion of swallowed air and the time has come for diet. As he passes through the corticoid withdrawal phase and assumes a decreased urine nitrogen excretion rate, his body becomes extremely avid for exogenous calories. This is usually manifested by an increase in appetite, an interest in food and resumption of normal peristaltic activity. The provision of exogenous calories now becomes essential to recovery and for the production of anabolism. The calories ideally should be supplied at the rate of 200 calories for each gram of assimilable nitrogen in the diet. But calorie-nitrogen ratios somewhat lower than this will support anabolism.

In normal convalescence, after surgery of the abdomen or thorax or extensive surgery of the extremities, the patient's initial dietary effort during the corticoid withdrawal phase will give him nitrogen intakes in the range of 3 to 7 gm. per day with caloric intakes between 500 and 1500 calories. After two or three days of such an intake in the form of semisolid food, the patient will resume a normal mixed diet, having a caloric intake of approximately 2400 with a nitrogen intake in the range of 12 gm. In the case of a female, these figures are all somewhat lower.

During early anabolism, the patient's weight will remain seemingly stationary at a level of from 1 to 3 kg. below the pre-operative weight. If very careful weight measurement are made daily, it will be found that weight is not stationary but is instead increasing very slowly at a rate determined by the positive nitrogen balance. Each gram of nitrogen loaded represents

retain ingested or infused water. This tendency passes off and the patient's metabolism of water returns to normal within a day or two unless complicating systemic or surgical factors are present.

The Wound. In a clean primary wound of the type considered as the "norm" here, the resumption in tensile strength occurs during the sharp upswing in nitrogen metabolism described below. This coincidence is lacking in more complex settings, however, and we estimate that, on a mixed general surgical service caring for trauma as well as elective surgery, about two-thirds of the wounds gain their tensile strength during continued nitrogen negativity. Resumption of tensile strength is the result of fibroblastic activity and the formation of intercellular collagen which later becomes increased in the mature scar. The wound at seven days is a thin line appearing much as it did when originally sutured, at five to seven weeks it is a red, raised, thickened cicatrix.

Metabolism. Although the steroidal response is usually short lived, the metabolic change apparently initiated by it may outlast it by many days. In the moderate mid-scale trauma we are using as a prototype, the nitrogen reversal often occurs within a day or two after subsidence of the adrenal discharge. In other circumstances, particularly in burns and fractures, as described subsequently, the association is less close. In any case, at some time after this release from steroidal influences, and only after its release, there occur two metabolic events which symbolize the changing metabolism of recovery.

The first is a reduction in the urinary nitrogen excretion rate. It is the occurrence of this reduction in urinary nitrogen excretion rate, together with a rise in eosinophils and a fall in urine steroid excretion, which has caused this early reversion toward more normal metabolism to be called "the corticoid-withdrawal phase." When the events happen together, the picture closely resembles that produced when large doses of ACTH or cortisone are withdrawn from a normal individual. The urinary nitrogen excretion rate is suddenly reduced from rates of 14 to 20 gm a day down to rates of from 5 to 7 gm. a day, over a period of one to two days. This indicates a sweeping change in nitrogen metabolism and protein dynamics and if intake now rises with the resumption of eating, the patient rapidly assumes a positive nitrogen balance.

The second event is a release of water and

salt from the early post-traumatic conservation. Urine sodium concentrations rise and the excretion of water loads is prompt and more clearly related to serum osmolarity. In some instances, these events constitute a clear-cut diuresis phase. In other cases, the changes are delayed and less clear-cut though of equal importance in signaling the normal progress of convalescence.

The positive nitrogen balance period which now ensues has been called "the spontaneous anabolic phase of convalescence" and is a period of surpassing importance to the recovery of the individual. If the patient does not go into positive nitrogen balance, he will not regain muscular mass and strength and he will not recover. In such an event, the dynamic progress of convalescence may be thought of as "stalled." The patient will develop chronic weakness and apathy, will not permit mobilization, weight loss will continue and the picture of convalescent failure will ensue, so common in association with late burns, sepsis and starvation. The rate at which protein is synthesized during anabolism averages in the neighborhood of 3 to 5 gm. of nitrogen per 70 kg. body weight per day. Instances have been reported in which spontaneous anabolism persisted for several weeks at a somewhat higher rate, even as high as 8 gm of nitrogen per 70 kg per day, an unusually rapid rate.

The relationship of nitrogen metabolism to the recovery of the patient, on the one hand, and to the healing of the wound, on the other, has been the source of much misunderstanding. There has been an impression that the loss of nitrogen in the early phase of convalescence is harmful to the patient and should be combated. If the individual has long been depleted by chronic disease, a strongly negative nitrogen balance (such as that produced by sepsis) is unquestionably deleterious, as further acute tissue wasting superimposed on chronic starvation results in visceral damage, particularly a fatty liver. In the well nourished, the brisk loss of nitrogen which follows trauma is usually correlated with a satisfactory convalescence. Although the patient might be "better off" if he did not lose this nitrogen, such has never been proved. By large intravenous loads of nitrogen (as protein hydrolysate) and glucose, the total losses may be reduced, the excretion rate, however, is further increased. Benefit to the patient by such procedures is not readily demonstrable. Much more important in the consideration

the application of surgical skill as a whole, of which metabolic care forms but one aspect.

Extrarenal Losses. Since the first chemical observations in surgical patients, the subject of dehydration has occupied a great deal of attention in the surgical literature. Surgical dehydration most commonly occurs as a result of gastric or intestinal obstruction with vomiting of intestinal juices. Other causes are diarrhea and intestinal and pancreatic fistulae. These represent extrarenal losses of fluid from the body and the term is used to indicate those losses of fluid, salt and protein from the body which take place outside the kidney and outside the normal renal regulatory mechanism. Occasionally, such collections as massive recurrent pleural transudate, portal vein obstruction with massive accumulation of exudate in the bowel or appendiceal peritonitis produce a picture of which dehydration forms a part. Under special circumstances, abnormalities of renal function may produce severe dehydration through the kidneys themselves. The recovery phase of post-traumatic renal insufficiency furnishes an example of unregulated water and salt loss through the kidney. With this exception, most dehydrating conditions in surgery involve extrarenal losses.

The term "dehydration" has come to be loosely used. Dehydration without salt loss is rare in surgery, being largely due to pulmonary loss in high ambient temperatures. When it occurs, it produces marked serum hypertonicity with hyperchloremia, hypernatremia and uremia. A similar picture is produced by injudicious tube feeding in the unconscious patient. Prompt treatment with intravenous dextrose in water is most effective in pure dehydration. The commoner situation is dehydration due to loss of water and salt, the latter largely extracellular.

In no phase of surgery is the concept of "metabolic balance" more aptly brought to the bedside than in the management of the patient with large extrarenal losses. The objective of the attending surgeon should be to achieve perfect balance. By this is not meant nitrogen balance. It is almost impossible in such a patient to achieve anything that even approaches positive nitrogen balance. In a patient with acute intestinal obstruction, losing liters of salt-rich fluid each day, it is folly to waste time over a consideration of calories or nitrogen balance. When the acute situation has been brought under control

and the patient is again eating normally, his nitrogen balance will take care of itself.

Rather, the concept of "metabolic balance" in taking care of such patients is devoted to their balance of water and salt. The salts involved theoretically include the entire gamut of substances which are found in body fluids: sodium, chloride, potassium, magnesium, phosphate, sulfate, calcium and zinc; these could all be mentioned but we have no way of measuring most of these substances. If the surgeon will devote his unstinted attention to the balances of sodium, chloride and potassium, avoid overadministration of water, maintain blood volume and colloid osmotic pressure, he can guide his patient through the most massive disorders of water and electrolyte metabolism and emerge successful.

The first step is to measure the patient's intake and output with maximum accuracy. The measurement of fluid volumes should never be incomplete or inaccurate and on a surgical service equipped with such a simple device as a hollow container there is no excuse for ignorance as to the amount of fluid which has come out of the various orifices of the patient. If there are copious exudates in the dressings, vomitus on the sheets and pillow cases or diarrheal stools in the bed, such measurement becomes impossible but an observant nurse or doctor can make an educated estimate which is better than nothing. An estimate of the salt content of the collected discharges can be made on the basis of data documented in the literature or by direct analysis. The following general rules hold for the gastrointestinal tract:

Chloride—

100 mEq /l. throughout

Sodium—

100 mEq /l. throughout

Potassium—

Stomach 15 mEq /l

Small bowel 15 mEq /l except in small bowel obstruction or ileostomy diarrhea in which this may reach 70 mEq /l.

Secondly, the patient's weight should be followed closely. Weighing every day, or at least three times a week, is essential. Rapid gains or losses are undesirable, indicating massive fluid shifts. In the unstressed starving patient a slow loss of about 150 gm.

about 30 gm of lean wet tissue. For this reason a positive nitrogen balance of 5 gm per day, a high rate of spontaneous anabolism, will result in the accumulation of only 150 gm. of weight per day. On such a basis it takes approximately a week to gain 1 kg. Minor fluctuations in water balance and daily happenstance differences in the time or condition of weighing will mask this small rate of gain unless special measures are taken to observe it.

The most important abnormalities in convalescence during this phase are continued sepsis, continued activity of parenchymatous visceral disease, hemorrhage and disorders of the intestinal tract, particularly diarrhea, obstruction and paralytic ileus. All of these either increase the length of the period of catabolism, or postpone anabolism by lowering the ability of the gastrointestinal tract to resume its functions of ingestion and assimilation.

FAT GAIN: LATE CONVALESCENCE

Endocrinology. Little is known about the endocrinology of late convalescence. In the female, following extensive injury, surgery or burns, the male-type hair growth characteristic of the catabolic phase disappears and the female physical appearances return. Normal menses likewise return. The relationship of this gonadal renaissance to the other metabolic changes is uncertain.

The Wound. During nitrogen anabolism the wound becomes a red, raised cicatrix, often somewhat sensitive to the touch. As the patient passes into the later phase of convalescence, the wound gradually broadens, softens, turns white and may become concave or wrinkled. The fine suture marks often are obliterated completely.

Metabolism and Clinical Management. During this time, the patient is observed to have returned to zero nitrogen balance if convalescence has been normal and complete. Zero nitrogen balance is the normal state of the intact adult without gains or losses of weight.

Despite zero balance of nitrogen, potassium and sodium, these being the elements which we have considered throughout, the patient continues to gain weight. Measurements of total body water demonstrate that body water is constant during this period of weight gain, which indicates that the weight gain is due to accumulation of fat. When a patient has been chronically or severely ill or has undergone major surgery which has been followed by resumption of

normal gastrointestinal function, no elaborate methods are needed to determine that fat is being gained during this time. Normal body contours are restored and clothes fit once again.

The patient quite regularly leaves the hospital during the spontaneous anabolic phase of convalescence. For the body to regain fat normally, the caloric intake must be significantly in excess of the daily energy output. If a patient is "borderline" as to calories because of some disorder of the gastrointestinal tract, premature return to work will interfere with fat gain, the patient will appear to have had a normal convalescence in every other respect, but he will not regain his normal weight. An example would be digestive disorders after subtotal gastrectomy. Therefore, if an individual is not doing well as regards appetite and caloric intake, he should be discouraged from assuming full activity until weight has been restored.

COMMON ABNORMALITIES OF CONVALESCENCE

In some of the common abnormalities of convalescence, the basis of care lies in an understanding of the variations which they present from the normal endocrinology and metabolism of convalescence. In many instances such as renal failure, dehydration from extrarenal loss, fractures and sepsis, there are many details of pathogenesis, diagnosis and daily care which will not be mentioned. In all instances, the surgeon must realize that surgical judgment based upon a careful history, an accurate examination of the patient, intelligent selection and evaluation of laboratory work and x-ray examinations must take first place in his care. Sick surgical patients are problems in surgery first. Their metabolic disorders may be of central importance in their recovery, but without good surgical judgment, metabolic care is wasted. A patient with continued fever, continued endocrine activity, continued high nitrogen loss in the urine, continued conservation of sodium, all due to a subdiaphragmatic abscess, must have the abscess suspected, diagnosed and then drained. The adequacy of his metabolic care may determine survival in the end, but competent surgery comes first. If disease is overlooked or surgery clumsily performed, all else is in vain. By the same token, it avails little if body chemistry is normal while untreated thromboembolism continues its lethal course unrecognized. Patients are helped by

of ammonium chloride and potassium chloride and by the conscientious replacement of extrarenal losses of chloride and of sodium is the most effective prevention of alkalemia that must be taken of sodium.

Hypokalemic alkalosis characteristically follows a period of potassium deprivation when urinary potassium loss is increased, as in the postoperative state and in the presence of extrarenal potassium loss, such as occurs in upper gastrointestinal disease. But the full-blown syndrome can occur with the loss of only 100 mEq. of potassium if alkalosis is sudden and severe. The replacement of potassium is clearly of importance. Amounts as great as 120 mEq. per day may be given intravenously in treatment. *But the effect of potassium administration on serum potassium will be disappointing if the alkalosis remains uncorrected.* Fortunately, potassium chloride achieves both objectives simultaneously.

Operative stress makes hypokalemic alkalosis much more severe. The syndrome is most commonly seen in postoperative patients. The administration of ACTH to alkalotic subjects produces a worsening of the alkalosis and hypokalemia. It is thus clear that tissue stress plays some role here and it is our interpretation that stress acts by blocking the urinary sodium excretion (aldosterone effect) which would otherwise help to compensate for the alkalosis. The important point again is to avoid surgery in alkalotic patients until their alkalosis is corrected. We regard any preoperative carbon dioxide concentration in plasma over 30 mM/l. as dangerous in this regard.

Finally, the electrocardiograph is useful and provides a check on such patients at night or at times when serum potassium concentration is hard to measure, but the electrocardiographic changes are not due to changes in the serum potassium concentration alone and an electrocardiogram cannot replace quantitative analysis.

The recovery of patients with hypokalemic alkalosis does not depend solely on restoration of the chemical values of the blood or the electrocardiogram to normal, but instead on solution of the basic problem of gastrointestinal function. The patient's life is threatened by hypokalemic alkalosis and its prevention or treatment is of first-rank importance, but the restoration of normal gastrointestinal function must come also to produce recovery. The repair of the hypo-

kalemia will help promote resumption of normal neuromuscular function in the gut as well as the heart.

Hypotonicity: The Low Sodium Syndromes. With the increasing use of flame photometry for the study of plasma base patterns, there has been observed a large group of surgical patients with low serum sodium concentrations, often as a feature of severe illness. Since the sodium ion concentration is the most important single determinant in the serum osmolality, a patient with a low serum sodium usually has a hypotonic serum and extracellular fluid with an excess of water both within and without cells. Not infrequently a high serum potassium concentration is observed with the low sodium. Since it is one of the functions of the life process to provide cellular energy which maintains a high potassium concentration and low sodium concentration within the cell and the reverse outside, it is evident that one of the manifestations of cell illness and death will be the abolition of this gradient, a fact histochemically established by many observers. Because of this fact, a low serum sodium concentration is often associated with severe illness and its passive repair by sodium infusion quite unavailing. The repair of the primary pathologic process is followed by restoration to health and isotonicity together. Under other circumstances, an attempt to restore the sodium level may be lifesaving. It is, therefore, worth while to discriminate among the various hypotonic syndromes.

1. Outright *adrenal failure* involves unregulated urinary sodium loss as has been mentioned. Analysis of the urine for sodium is, therefore, the first step in differential diagnosis of hyponatremia. If, in the presence of a serum sodium concentration below 130 mEq./l., the urine sodium, in the absence of infusion, is over 30 to 50 mEq./l., adrenal failure or renal failure should be suspected, and suitable differential study should be undertaken. As a first step in this study, the response of the renal sodium output to DOCA is useful in discriminating renal from adrenal failure.

2. Large *extrarenal losses* of sodium can lead to a low serum sodium, particularly if replaced inadvisedly by a large amount of sodium-free water.

3. In the presence of uremia with a high nonprotein nitrogen or diabetes with a high sugar or possibly other situations producing *high crystalloid concentrations*, mild hyponatremia can coexist with serum isotonicity.

a day, as fat is oxidized, is to be expected until oral intake and anabolism are restored.

Thirdly, do not attempt daily urinary electrolyte loss replacement. It is a great mistake to restore to the patient the following day the amount of water or sodium lost in the urine the previous day. Renal excretory mechanisms for sodium, chloride and water are in part regulatory of extracellular volume and acid-base balance. The result of readministration of the sodium excreted in diuresis can readily be imagined. If the patient is having very large urine volumes, it is also unnecessary to try to restore them each day unless one of the very rare renal tubular lesions is present. In most surgical patients, high volumes or concentrations in the urine indicate important renal compensation for irregularities of intake. For this reason, we allow 40 mEq. of sodium, 40 of chloride, 40 of potassium and 1200 cc. of fluid each day for the urine output. This is a sound basis for treatment and will avoid serious error if renal function is normal. Insensible loss through skin and lungs totals about 750 cc per day in a normal-sized adult male, 500 cc for the female. If there is fever, hot weather or dyspnea, this may be tremendously increased. Dyspnea with fever is the most effective combination in increasing the extrarenal loss of water through the lungs, to figures as high as 2000 cc. per day.

Armed with a knowledge of what has come out of the patient, and with an estimate of the extracellular concentrations remaining, the surgeon can approach his daily intravenous therapy with accuracy and conviction. Under conditions of gastric obstruction, intestinal obstruction or diarrhea, the amount of fluids required per day may, of course, be massive, running as high as 8 to 10 liters in certain instances. By sharp contrast, the small, chronically ill female with congestive failure who has been vomiting from digitalis toxicity, may be overtreated if she receives 150 cc. of saline solution. Clarity of concept and accuracy of plan are essential!

If the patient comes upon the scene with established dehydration, the situation is much more complicated because the static debt of the patient must be made up during the course of the first few days, during which maintenance is also essential. The most important rule in a large experience with such cases has been to avoid the temptation to make up the entire static debt too suddenly or on the first day. Patients be-

come adjusted to lower levels of extracellular volume and they also become adjusted to some degree of serum hypotonicity. As has been said so aptly, the acutely unbalanced patient should be "nudged," not "swept," in the right direction. If the patient is an older individual with some degree of heart disease, the attempt to restore all past losses in one day may well result in a fatal outcome. As in all things in medicine, a careful history of intake and loss will set the stage for intelligent treatment. A weight gain for three to four days is to be expected as the debt is restored. This is the only exception to the basic rule of parenteral therapy: avoid weight gain.

Potassium Loss, Alkalosis, Hypokaliemia. In the past ten years there has become recognized a syndrome, usually in postoperative patients, consisting of distention, ileus, lethargy, fever, weakness, dehydration and electrocardiographic evidences of altered neuromuscular excitability. With this there is found a remarkable chemical situation consisting of metabolic alkalosis (a high carbon dioxide with normal or high sodium and often a low chloride), hypokaliemia (a low plasma potassium concentration in the range of 2.5 to 3.5 mEq. per liter) and an acid urine, seemingly paradoxical. Some degree of azotemia may coexist if dehydration is severe.

A considerable controversy has turned on this matter, particularly on the question of whether the potassium loss produces the alkalosis or the alkalosis lowers the potassium concentration and, indeed, on the central question of the role of potassium loss itself in the syndrome. There are several important facts which have emerged and which permit an understanding of the situation and, better still, effective prevention and treatment.

Hypokalemic alkalosis usually occurs in patients who have been alkalemic prior to surgery, or in those who have had an extrarenal loss pattern after surgery which could be expected to produce alkalosis. Examples are patients with obstructed duodenal ulcer with preoperative alkalosis, or those having upper gastrointestinal surgery (pancreas, stomach) in whom postoperative gastrointestinal loss has been predominantly gastric juice. Alkalosis can be demonstrated to lower the plasma potassium concentration experimentally. In most surgical patients with this disorder, the alkalosis appears to be the important primary event. The *prevention of alkalosis* by the preoperative use

intestinal cancer and chronic congestive heart failure. Though these three entities are seemingly of far different etiology, their effects on body composition are similar. There is a loss of weight due to loss of both fat and lean tissue. After a few months of illness, most of the available body fat has been mobilized and oxidized. There is, therefore, a relative increase in body water, largely extracellular, because of the loss of fat which occupies the nonaqueous phase of body composition. In addition, the chronically depleted patient shows a marked tendency to retain salt and water. This is responsible for starvation edema. If there is disease of heart or liver, this water and salt retention is greatly accentuated, as has been known for centuries. The chronically depleted patient approaching surgery is, therefore, a patient who has too little fat, too little lean tissue, too much body water, too much of which is extracellular water, and too much extracellular salt (sodium and chloride) in his body. His response to trauma is quite characteristic. The depression of eosinophils and rise in blood and urine steroids are quite active but they are very transient. The quantitative steroid changes are not great and they rapidly revert to normal. The loss of nitrogen in the urine is not great and the patient will return to positive balance with low calorie-nitrogen ratios. If he is managed "gently" and water and salt overloading avoided, the chronically depleted patient will pass through his surgical experience quite uneventfully and wound healing will usually be quite normal.

Although such careful management will usually produce a well healed wound and a successful convalescence, the over-all incidence of wound dehiscence, or primary failure of fibroblastic union, is slightly higher in this group than in previously well nourished subjects. This is especially true of patients with cancer, particularly if the disease has reached the inoperable stage. Nonetheless, the incidence of dehiscence in the group as a whole is low in absolute terms—about 2 per cent. The remarkable thing is that given good technique in closing such a wound, adequate vitamins, avoidance of salt overloading, the great majority of these wounds do heal well despite advanced tissue wasting—an example of the meaning of the high biologic priority of the wound in the early phase of convalescence.

If blood loss has been a part of the depleting disease process, the blood volume will be low, particularly in the red cell fraction.

If blood loss has not been prominent, these wasted patients commonly have a normal or high blood volume with a definitely elevated plasma volume and a slightly low hematocrit reading. Massive transfusion of these patients preoperatively is based on the impression, often erroneous, that they have a chronic blood volume deficit. This impression is based on the slightly low hematocrit reading. The transfusion will load down the circulation with excess fluid, only to embarrass anesthetic and postoperative management. If these patients' depleting process has been accompanied by true hemorrhage, their red cell mass may be very low and the judicious use of whole blood transfusions or of packed cells may be quite valuable. Beware of sudden increases in blood volume in depleted, elderly patients! Again, "nudge," don't "swamp," the depleted individual.

Depleted patients have lost their "metabolic reserve" and are extremely sensitive to several metabolic challenges. First among these is infection. Such patients have little ability to withstand the catabolic ravages of sepsis and if they are overtaken by invasive sepsis they will frequently very rapidly succumb. Second is massive injury. Such patients can withstand gentle management and surgery which is not too extensive; their wounds heal nicely. If the tissue insult is too great, such patients do not rally well, will develop renal, hepatic or pulmonary failure and failure of wound union, and will succumb. Thirdly, these patients are very vulnerable to overadministration of water and salt; serious positive balances are quickly established, with resultant hemodilution, hypoproteinemia and pulmonary edema. Cough reflexes are poor, effort small and aspiration common. The cause of death observed at postmortem examination usually includes "bronchopneumonia" or interstitial pneumonitis. There may also be pulmonary edema and a mixed renal lesion. In some instances, the pathologist can cast little light on the mechanism of death. It is for these reasons that staging of procedures and dexterous gentle surgery with careful metabolic management are of such importance in chronically depleted individuals.

It should be emphasized that patients who have lost one-tenth to one-eighth of body weight largely as fat, and who still have strength to walk vigorously around the ward with good vital capacity and normal extracellular chemical balance, are excellent risks for extensive surgery. They are in many ways a better risk for surgery than is the

The abnormal crystalloid fills up the solute total to normal.

4 After *trauma*, it is a common phenomenon to find the sodium concentration low and the potassium high. The range here is not great.

5. If none of the above four obtains (adrenal-renal failure, extrarenal loss, isotonic hyponatremia due to crystalloid excess, normal post-traumatic "shift"), one is probably dealing with hyponatremia as a manifestation of diffuse *cellular illness* and the problem, therapeutically, is whether or not the use of concentrated salt solution is advisable.

If the patient is *edematous* and suffering from disease of heart, liver or kidneys, the use of concentrated salt is very dangerous. There is a wealth of evidence that such patients have an excess of body sodium already. Their basic defect is an inability to excrete water and an inability to exclude sodium from cells.

If the patient is *not edematous*, a cautious trial of 300 cc. of a 3 per cent solution of sodium chloride daily for three days, with observation of clinical and chemical effects, is justified. Particular attention should be paid not only to the serum sodium response and urine output but also to the early signs of pulmonary edema and to the hypoproteinemia which may result. If the patient has been on a low sodium diet and mercurial diuretics, the therapeutic trial is especially worth while, it should be realized that some degree of body deficit may be present, though rare.

In any case, it is of singular importance to bear in mind that general nutritional care is often of greater effectiveness than an exclusive interest in the serum sodium concentration alone. Repair of anemia, avitaminosis and hypoproteinemia and, above all, attention to caloric intake in the chronically ill may be the most effective steps in restoring the serum sodium to normal and the patient to normal health.

Prolonged Intravenous Feeding. If the patient's sepsis or extrarenal losses are controlled but surgical convalescence still cannot proceed because of gastrointestinal difficulty requiring prolonged intravenous feeding, a special nutritional setting is introduced. An example is to be found in such a situation as foreshortening of the bowel, malfunctioning gastrointestinal anastomosis, esophageal obstruction or chronic peritoneal infection with ileus.

Total intravenous feeding is never wholly

successful in the sense of providing sufficient calories and nitrogen to achieve anabolism, resumption of weight and strength. It appears that introduction of food into the gastrointestinal tract, as planned by nature, is still necessary. It is important to emphasize that, in certain surgical conditions, introduction of food into the gastrointestinal tract may be done by means of gastrostomy or jejunostomy, making prolonged intravenous feeding unnecessary. Occasional failure to recall the importance of this procedure or inability to perform this operation with the accuracy and gentleness required has produced tragic results.

When such an operation is inadvisable because of more distal disease in the gastrointestinal tract, prolonged intravenous feeding may be undertaken with the following general rules in mind:

Water, sodium, chloride and potassium should be provided daily.

The administration of water and salt each day should be carefully gauged by measured observation of the patient's weight and of extrarenal losses. The patient should not gain or lose weight rapidly. He should be expected to lose about 150 to 200 gm a day as his fat stores are burned.

One whole blood transfusion should be given approximately each week to provide trace minerals, electrolytes and erythrocytes not found in pharmacologic solutions.

Adequate intake of vitamins is vital.

If the patient is unstressed, he will anabolize from intravenous protein hydrolysate if adequate calories are also supplied. The provision of amino acids in the form of protein hydrolysates finds its maximal usefulness here.

The provision of adequate calories is a challenge. Concentrated glucose solution given into a caval catheter and the use of alcohol and fat emulsion may all be useful.

But, above all, the patient should begin enteral ingestion of food as soon as possible. During the transition phase one should remember that parenteral provision of glucose "kills appetite." In a chronically ill patient whose stomach is not accustomed to accepting food and who has lost the habit of appetite, it is essential to omit the provision of intravenous calories for a few days so as to stimulate appetite as the enteric channel is reopened.

Preoperative Bodily Depletion. The surgeon frequently must operate upon patients depleted by chronic disease. Commonest among these are chronic sepsis, gastro-

intracapsular subcapital femoral neck fracture, with its minimal metabolic response, is less apt to heal to good union.

The extensive wound of war may take any anatomic form. Very typical of a large number of the seriously wounded is a wound due to multiple penetrating fragments of artillery, mortar or mine missiles and involving injuries to the skeleton, the body cavities and hollow viscera. The result is massive blood loss, contamination of injured tissues and large cross-sectional trauma.

From the evidences available, the endocrine response appears also to be massive. The amount of adrenal medullary activity observed in shocked soldiers is great and this would lead us to believe that the cortical steroid output also is imposing although fewer data are available. Eosinophil counts are low for many days and when they gradually resume a higher value they may then be observed to be at extremely high levels (3000 to 4000 cells per cu. mm.) for many days or weeks. The amount of surgery involved is great as fractures must be set, bleeding stopped, devitalized tissue debrided and hollow viscera either repaired or exteriorized. The actual extent of the trauma, viewed as a physiologic insult to the patient, is the product of the initial cross-sectional trauma involved, the total blood lost, the duration of time which ensues between the initial injury and the completion of definitive surgery and the details of the definitive surgery itself. The latter includes debridement and immobilization.

The metabolic response which ensues is, therefore, doubly large, not only because the trauma is large but because it characteristically occurs in the athletic, healthy and well nourished young adult male. Remarkable degrees of body wasting are observed. The patient may lose 25 per cent of his body weight in the first month. If sepsis can be controlled and visceral function (particularly renal function) maintained, the patient will convalesce if he finally has access to adequate oral nutrition. Only through this medium can convalescence be assured.

Special problems of shock, the blood volume and renal failure present themselves regularly among the severely wounded. The three are interrelated for the clear reason that an accurate knowledge of blood volume physiology is essential to the treatment of shock, renal failure usually follows shock and the post-trauma metabolism is a

vicious cause of hyperkalemia in this setting.

Continued oligemia is the commonest cause of continued shock. The term "irreversible shock" should not be used in the case of these patients. More often than not, it merely hides ignorance of other factors such as pneumothorax, hemopericardium or continued uncontrolled hemorrhage, all of which are susceptible to treatment, whereas the concept of irreversible shock only connotes hopelessness.

Once shock has developed, the amount of transfusion needed to restore the circulation is greater than the established deficit, be it estimated by history or measured directly.

If oliguria persists, the steps outlined should be followed with care to avoid overloading the patient with intravenous therapy.

Burns. The metabolic variants of a burn are most clearly seen in two respects. First, the water and salt picture is different from that associated with any other form of trauma. A major burn produces a large accumulation of edema under the area of thermal trauma, owing to thermal damage to capillaries. This segregates a large volume of water and salt which is derived from the plasma volume, reducing the blood volume with a resulting high hematocrit reading. Oligemic shock supervenes unless adequate plasma volume support is carried out with some sort of colloid-containing fluid, of which plasma or one of the plasma expanders is by far the most commonly used. When given into the plasma to maintain plasma volume, these in turn leak out in part into the burn. The result is a large accumulation of water and salt which produces an early weight gain and strongly positive water and salt balances. Positive sodium balances in patients with major burns, early and adequately treated, may range between 500 and 1500 mEq. in the first forty-eight hours, depending on details of therapy. The weight gain which results is accordingly unique. It averages, in our experience, very close to 10 per cent of the initial body weight of the patient and this correlates with the fact that the extracellular fluid space is expanded to approximately twice normal. After two to five days, this fluid is excreted, weight rapidly falls and a convalescent pattern demanding caloric intake and more reminiscent of other forms of trauma is resumed. If renal insufficiency occurs and diuresis does not take place, convalescence is interrupted and recovery is rare.

overfed, obese man or woman with a tremendous omentum full of fat, decreased diaphragmatic excursion and flabby muscles. It is rightly emphasized by the nutritionists that the great hazard of the American population is not malnutrition but overnutrition and this is very true in surgery.

Infection. Acute sepsis without trauma has in itself many of the metabolic and endocrine aspects of acute trauma. There is a speeding up of the metabolic wheel, resulting in rapid loss of weight due to oxidation of fat and loss of nitrogen. There is an adrenal secretory increase and eosinopenia. There is also a clear-cut tendency to retain water and sodium. If sepsis complicates surgery and is rapid in onset after surgery, there is a marked intensification of the clinical and metabolic effects of trauma. The patient looks much sicker, his fever is higher, the nitrogen loss is increased and body wasting is even more rapid. If the infection is quickly brought under control, as by drainage of an abscess, exteriorization of damaged bowel or effective administration of antibiotics, the patient will then pass into a recovery phase quite normally.

When the sepsis exists for a longer period, as in unresolved peritonitis, infected open wounds, or osteomyelitis after fracture, the continuation of sepsis amounts to an indefinite prolongation of the catabolic phase of metabolism. With continued sepsis and purulent discharge, even though the temperature be normal, the pulse is elevated and measurements of metabolism show that the eosinophil count is down, the serum steroid level remains elevated, wound losses may be considerable and the urinary nitrogen loss persists. The presence of sepsis thus prolongs the catabolic phase after trauma and, more importantly, postpones for as long as sepsis is active the corticoid-withdrawal phase and resumption of normal anabolism.

This fact has several extremely important corollaries in clinical management. The obligatory catabolism of sepsis in its acute febrile phases seems to be a counterpart of the obligatory catabolism following injury in that it is difficult to affect either the clinical course of the disease or the rate of nitrogen loss in the urine by the provision of large intakes. But as the acute infection is initially controlled, the patient quickly passes into a period in which intake is of critical importance. If chronic infection is present, the provision of this intake may be difficult and threatening nutritional deficits develop rapidly. A ready example is found

in the late burn with infected open wounds. After only a week or two of thoughtless neglect, such a patient will show anemia, avitaminosis, hypoproteinemia and edema. Under such circumstances, the administration of large intakes may be extremely beneficial in reducing the rate of body wasting, even though anabolism has not yet been produced. Patients with chronic septic processes furnish the chief examples in general surgery of the usefulness of forced feeding, an indwelling gastric tube being used when needed.

Fractures and Extensive Wounds. Certain endocrine and metabolic features of fractures, extensive wounds and burns are worthy of mention because each has endocrine and metabolic characteristics which set it apart from the stress of primary elective anesthetized soft tissue trauma. All three are examples of the importance of the wound in determining the depth, duration and details of early catabolism despite the similarity of their initial endocrinology.

Midshaft fractures in young individuals produce a very intense nitrogen catabolism which far outlasts the early period of endocrine activity or the period of starvation. Changes in eosinophils and blood and urine steroids may be no more prolonged than after soft tissue trauma. The prolonged loss of nitrogen, calcium and phosphorus is quite remarkable. The loss of calcium and phosphorus is traceable in part to the skeletal immobilization which is intrinsic in treatment and in part to release of these electrolytes from the fracture site itself. The more prolonged nature of the wound-healing process required to restore the injured part to tensile integrity is apparently associated with a much more prolonged phase of nitrogen loss. It is for this reason that body wasting is more noticeable and that a much longer late phase of refeeding is essential. There is also good evidence that if intakes can be maintained at a maximal level after the first week or so, the net loss from the body is reduced even though the absolute nitrogen excretion rate is increased.

Fractures which produce little systemic response are most clearly seen in the intracapsular subcapital femoral neck fracture. Here, a fracture which occupies as much bone cross section as a midshaft fracture is associated with very little muscle disorganization or hematoma because of its intracapsular position. The relatively minor blood supply of the region is noteworthy. It is possibly a significant correlation that the

limited time not to exceed five days. The patient should be kept on antibiotics and given suitable gastric antacid therapy to avoid the commonest complications which are sepsis and bleeding peptic ulcer. At the end of that time, the hormone should be "tapered" off and the patient's own adrenal response tested by the response to ACTH and by appropriate urine steroid measurements. Precise localization and assessment of the defect is then possible. Prolonged administration of ACTH or cortisone results in relative adrenal insufficiency when the drug is stopped. This must be taken into consideration in all patients operated upon after prolonged administration of these hormones.

Renal Failure. The subject of metabolism in surgical patients with acute or chronic renal disease is one of considerable importance in present-day surgery. Lower nephron nephrosis, otherwise referred to as ischemic nephrosis, post-traumatic renal insufficiency, pigment nephrosis, the crush syndrome or tubular degeneration, is most commonly observed in patients after wounds or operations. All these terms are to some extent synonymous and when applied to the severely injured patient or the patient who has been in shock after surgery, they indicate minor clinical variations in a renal picture most simply referred to as acute renal failure. Over two-thirds of the incidences of occurrence of this syndrome arise from either surgical or obstetric episodes. The commonest causes are massive injury with hemoglobinuria, myoglobinuria and shock, surgical shock itself, mismatched transfusions and obstetric complications involving hemorrhage such as premature separation of the placenta.

The treatment of such patients centers on early diagnosis. The diagnosis that the patient is passing into a phase of renal disease, rather than oliguria due to hypotension and dehydration, rests upon the finding of a small and falling urine output at fixed specific gravity despite the restoration of normal blood pressure and hydration, with a rising blood urea and serum potassium value.

Once this diagnosis is suspected the patient should be treated by "balance," avoiding any sudden weight gains or losses which indicate sudden shifts in body water volume. Early recognition of the problem and adherence to this principle during the first forty-eight hours may be lifesaving. Those in charge of the patient all too frequently

suffer under the delusion that large water or salt infusions will "open" or "flush out" the kidneys. If hydration, blood volume and blood pressure are normal the kidneys will resume function when they can; large infusions (over 1000 cc. per day) only threaten life by overburdening the circulation.

Conservative therapy, avoiding overloading the patient with water and salt, maintaining water balance, maintaining normal blood volume and avoiding the prolongation of sepsis will be followed by spontaneous diuresis and recovery in a substantial fraction of the patients.

Increase in the blood level of urea and related compounds does not seem to do the patient a great deal of harm. The accumulation of potassium in the extracellular phase is the chief threat to life in this disease. The accumulation of metabolic acids producing acidosis is also extremely hazardous. The rate of accumulation of both is greatly accelerated after injury and they act synergistically. When these occur and the patient continues to be oliguric, treatment by ordinary measures is often unavailing. The patient should be referred or transferred to a center where renal insufficiency is frequently dealt with and where methods of artificially dialyzing these substances out of the blood are available. Early transfer is safe or feasible; procrastination based on false hope is fatal.

Summary. No single summarizing statement is possible. Normal endocrine and metabolic processes underlie surgical convalescence. Their understanding as normal phenomena is the key to a rational and effective treatment of the metabolic abnormalities which are so common in all fields of surgery

Second, the nitrogen-calorie relation resembles fractures in that there is a very prolonged period of nitrogen loss, loosely correlated with the duration of the unhealed wound. It long outlasts the period of steroidal activity. It lasts the length of time that the wound would ordinarily be expected to take to heal. If the open wound persists long after this time as small unhealed areas, it will be extremely difficult to heal. Here, as in the fracture, the provision of nutrition as soon as gastrointestinal acceptance occurs minimizes the body wasting.

Endocrine Disease. Shortly after the description of the importance of the adrenal steroids in postoperative endocrinology, the concept became widespread that adrenal failure would turn out to be a common cause of difficulties in surgical convalescence. Such has not been borne out by subsequent experience. Outright adrenal failure in patients previously unsuspected of endocrine disease is quite rare, but its importance cannot be overestimated for the individual patient in whom it occurs and there are lesser degrees of abnormality which are more common.

Adrenal failure after operation is manifested by high fever, tachycardia, hypotension, oliguria, shock and coma. Administration of large amounts of blood, plasma, antibiotics, water and salt is of some slight assistance, but results are remarkably non-specific. If the patient has some degree of visceral congestion initially, this massive administration of parenteral fluids will ultimately be fatal. By contrast, the response to intravenous hydrocortisone is so dramatic as to constitute one of the spectacular experiences of a surgical career.

The diagnosis of adrenal failure must, therefore, be considered in any patient who is not doing well after surgery. The eosinophil count should be made and, whenever possible, measurements of the blood and urine steroids should be carried out. If, within three days of surgery, and with an extremely ill patient, the eosinophil count is over 50 per cu. mm., a very high degree of alertness should be aroused.

Whether or not the eosinophil count is elevated, and if there is reasonable suspicion that other forms of hypotension and oliguria have been adequately considered and treated, a specific therapeutic trial with hydrocortisone given intravenously is indicated. It is always unfortunate when "blind" therapy is given for any condition in medicine or surgery. There are certain circumstances, however, in which the hazard is so

small, and the possible benefit so great if the diagnosis turns out to be correct, that blind therapy is justified. In the postoperative patient who has been accurately transfused, whose water balance has been carefully considered and adequately handled, whose airway and pulmonary and cardiac function show no important defects and who is bordering on shock or is in shock, the administration of hydrocortisone intravenously in a dose of 100 mg. in 500 cc. of a 5 per cent solution of dextrose in water is a justified procedure. A positive response is of tremendous significance.

In an acute emergency, the employment of cortisone or hydrocortisone is more rational than ACTH since the latter is unavailable if there is significant adrenal disease.

When the administration of hormone to surgical patients is used as a disguise for inadequate diagnosis, it is to be deplored. When intelligently applied it is, of course, useful. The cause of postoperative adrenal failure is most commonly subclinical Addison's disease or acute adrenal hemorrhage, the latter often associated with the use of anticoagulants.

When the adrenals are removed surgically, as in the treatment of carcinoma, one deals with postoperative hypoadrenocorticism which is treated with specific administration of adrenocortical hormones, the therapeutic pattern of which should mimic the normal metabolic and endocrine response to surgery.

Myxedema and diseases of the pituitary also are accompanied by postoperative "metabolic decompensation." If these are present, administration of appropriate hormones, either thyroid, ACTH or cortisone, should be carried out.

Chronically ill patients, such as the patient with the late burn, or the patient in the later phases of peritonitis with localized abscess formation, will frequently carry a resting high eosinophil count and, when operated upon, the eosinophil count will rise to extremely high levels, such as 2000 to 3000 per cu. mm. This does not indicate adrenal failure. Adrenal failure is manifested not only by a high eosinophil count, which is an isolated laboratory observation also producible by a variety of other mechanisms including allergy, but by actual metabolic changes, the most striking of which are failure to maintain blood pressure, unregulated loss of salt in the urine and fever.

Once the administration of hydrocortisone is started, it should be maintained for a

ANESTHESIOLOGY

By JOHN ADRIANI, M.D.

JOHN ADRIANI went from his home in Bridgeport, Connecticut, to Columbia University for his college and medical school degrees. A surgical internship and a fellowship in physiology paved the way for his training in anesthesiology. His interest has a broad base and recognizes the mutual cooperation necessary between surgeon and anesthesiologist for the best care of the patient. He has spent his professional life thus far in New Orleans where he directs anesthesiology in the medical schools of Tulane and Louisiana State University.

Anesthesia is an adjunct to patient care. Surgery, as it is now practiced, would hardly be possible without it. Although physical agents such as pressure, cold and electric currents may be used to induce anesthesia, the practical methods for its production entail the use of chemical substances which depress the activity of nervous tissue. These chemical agents either act systemically and depress the central nuclei or they act locally and block the activity of a nerve fiber when applied directly to its surface. Thus, anesthesia is recognized as *general* or *systemic* and *local*. More precisely, local anesthesia is referred to as *regional* or *conduction* anesthesia. Regional anesthesia is subdivided into types named according to the site of application of the drug used to produce it; namely, *spinal*, *epidural*, *paravertebral*, *nerve block*, *field block*, *infiltration* and *topical*.

To be surgically useful, an anesthetic drug or method of producing anesthesia must fulfill two purposes. (1) it must abolish reflex activity and other responses to stimuli and (2) it must provide muscle relaxation. A third requirement, loss of consciousness, is desirable but is not always necessary.

GENERAL ANESTHETICS

The general anesthetics are volatile substances which are administered by inhalation, or nonvolatile drugs which are administered by routes other than inhalation. The volatile drugs differ in pharmacologic characteristics from the nonvolatile. The members in each group are similar pharmacologically and are used for the same purposes.

The volatile drugs are complete anesthetics. They cause a blockade along the path from the periphery to the pain perception centers. The loss of sensibility is accompanied by a loss of consciousness. Loss of muscle tone of varying degrees is obtained, depending upon the potency of the drug. Volatile anesthetics are inert; that is, they are not altered by the cells. They are eliminated unchanged by exhalation. They are gases, or highly volatile liquids, which boil below 60° C. With the exception of nitrous oxide, currently used drugs are hydrocarbons, ethers or halogenated hydrocarbons. Three gases, nitrous oxide, ethylene and cyclopropane, and six liquids, ether, vinyl ether, chloroform, ethyl chloride, Fluothane and trichlorethylene, are used.

The nonvolatile drugs, on the other hand,

reservoir and the mask prevents return of expired gases and obviates rebreathing.

4. The closed method (Fig. 3) permits total rebreathing of gases and vapors. An inhaler composed of a mask and breathing bag is provided with a filter containing an absorbent (soda lime) for carbon dioxide. Oxygen to meet the metabolic requirements of the subject is supplied from a reservoir. Both the semiclosed and closed types of apparatus must be provided with metering devices (flow meters) to supply gases and vapors in desired proportions. The closed system is almost universally used for the administration of inhalation anesthetics in present-day practice.

Nonvolatile drugs are administered by routes other than inhalation. No satisfactory substances exist which can be administered orally which induce satisfactory surgical anesthesia. Most nonvolatile drugs used in conjunction with surgical anesthesia are administered rectally or intravenously. The narcotics and certain of the hypnotic drugs are administered subcutaneously or intramuscularly.

Anesthetics are protoplasmic poisons with three notable characteristics: they have a special predilection for nervous tissue, they ultimately affect all protoplasm as concentrations are increased and their action is reversible within limits. Once the drug is removed, the physiologic state of the cell

reverts to normal. This reversibility of action is extremely important. Overdosage of central nervous system depressants paralyzes the medullary centers. Death results from respiratory failure. The nervous system is depressed from above downward, that is, the cortex first, the midbrain next and then the medulla. If artificial respiration is promptly instituted and maintained after medullary paralysis occurs, the circulatory system remains intact. A dose exists for each drug, above that which causes paralysis of the medullary centers, which is lethal even though effective artificial respiration is performed. These doses vary from one drug to the other. What they are for man is not known. The concentration of ethyl ether which depresses the heart is several times that which causes medullary paralysis. On the other hand, concentrations of chloroform which depress the myocardium are close to those which paralyze the respiratory centers.

The progressive depression of the nervous system gives rise to a succession of reflex changes which are clinically useful in estimating the concentration of the drug in the nervous system. The disappearance and reappearance of these reflexes, as the concentration is varied, serve as a useful guide for the administration of anesthetics. The manner in which volatile drugs influence these reflex changes differs considerably from that of nonvolatile drugs. The changes caused by

Figure 2 Semiclosed technique. The semiclosed apparatus consists of (A) a mask and (B) a rubber breathing bag of 4- or 5-liter capacity and a source of anesthetic gas and oxygen (C). An exhalation valve (1) on top the mask allows exhaled gases to pass to the outside atmosphere. A valve (2) may be interposed between the mask and the reservoir to prevent rebreathing. Under these circumstances the minute volume exchange of the patient must be supplied continuously without interruption. This second valve is omitted in most apparatus used for anesthesia.

Figure 1 Insufflation technique. The volatile liquid is vaporized by bubbling air, oxygen or a mixture of an anesthetic gas and oxygen (A) through the container (B) and the mixture is conducted into the upper respiratory passages. In oral and pharyngeal surgery a cannula (D) conducts the anesthetic mixture into the mouth. A catheter may be used for nasopharyngeal or direct insufflation into an intratracheal catheter or cannula. (From *Adrian: Techniques and Procedures of Anesthesia*. Courtesy Charles C Thomas, Publisher.)

are incomplete anesthetics. None completely blocks the passage of impulses from the periphery to the thalamic nuclei. A hypnotic state, from which the patient may be roused, is obtained with therapeutic doses. Larger doses produce a more profound state of depression accompanied by amnesia and partial obtunding of reflex activity. Doses which abolish reflex activity and produce anesthesia in a surgical sense depress the medullary centers unduly and give rise to circulatory and respiratory depression. The nonvolatile drugs, unlike the volatile, cannot be used as sole agents for surgical anesthesia. In present-day practice it is common to combine nonvolatile with volatile drugs. The former provide sedation or basal narcosis, the latter, analgesia and suppression of reflex activity. One complements the other. The nonvolatile drugs are liquids whose boiling points are too high to permit adequate vaporization for inhalation, or they are solids. Chemically, the majority are aliphatic compounds, derivatives of urea or alkaloids. The aliphatic compounds are alcohols, halogenated alcohols or halogenated aldehydes. Numerous derivatives of urea are available, the most useful of which are the barbiturates. The alkaloids are narcotic substances; that is, they possess both analgesic and hypnotic properties. The analgesic power, however, is not sufficient to abolish reflexes and relieve sharp pain. Narcotics

thus possess little usefulness as surgical anesthetics. They do, however, induce a euphoric state which is utilized for preoperative sedation. An additive effect is obtained when narcotics are combined with less potent anesthetics such as nitrous oxide, which thereby facilitates their use. The narcotics are almost universally used for control of pain preoperatively or postoperatively.

METHODS OF ADMINISTERING GENERAL ANESTHETICS

Volatile anesthetics are administered by one or a combination of four different methods.

1. The open or drop method is adaptable for liquids. The liquid is vaporized on a gauze mesh, becomes mixed with air which serves as a vehicle and source of oxygen, and is inhaled.

2. The insufflation technique (Fig. 1) is suitable for both gases and vapors. A stream of gas or vapor, mixed with air or oxygen, is conducted into the oropharynx, nasopharynx or trachea by means of a catheter or a tube.

3. The semiclosed method (Fig. 2) is used for gases or vapors mixed with air or oxygen. A preformed mixture of gases and vapors is inhaled from a closed mask which communicates with a reservoir (breathing bag). The exhalations pass through a valve on top of the mask provided for the purpose. -A directional valve interposed between the

2 because the smaller muscles throughout the body, including those of the eye, lose their tone. The pupils are, then, centrally fixed. Respiration is altered little in planes 1 and 2 because both the intercostal muscles and the diaphragm remain active. As plane 3 is reached, intercostal activity is lost and respiration becomes diaphragmatic in quality. Muscle tone is diminished throughout the body. The pupils increase in size but are not widely dilated. Corneal reflexes are obtunded or abolished. There may be some elevation in pulse rate and a slight fall in blood pressure. Surgery necessitating relaxation of the large muscles may be performed in plane 3. In plane 4, complete relaxation of the large muscles and loss of all reflexes occur. Diaphragmatic activity is diminished; the pupils are widely dilated. Respiration is diaphragmatic, inspiration is quick, short and jerky and expiration is prolonged. The minute volume exchange is diminished.

In stage IV, the medullary centers are inactive. The respiratory center is the first of the medullary centers to become completely depressed and apnea results. Unless artificial respiration is instituted promptly, death results from the ensuing asphyxia. With most of the anesthetic drugs employed, the heart continues to beat after the onset of this stage if artificial respiration is instituted and maintained as soon as apnea occurs.

The cough reflex disappears as stage III is reached. The vomiting or gag reflex disappears at the same time. Tracheal and bronchial reflexes disappear in planes 2 and 3. Reflexes initiated by traction on the abdominal viscera, pleura, hilum, trachea or bronchi or by stimulation of the perineal structures disappear in plane 3 but may persist even into plane 4. When the anesthetic is discontinued, reflex activity returns in the reverse sequence. After the administration of ether for a long period, however, the order of return of reflexes is variable. Anoxia, carbon dioxide excess, heavy sedation and basal narcosis with nonvolatile drugs modify and invalidate the signs. The signs tend to vary with the extremes of age.

The electrical activity of the cerebral cortex is suppressed by anesthetics and hypnotics. The reduction in the cortical potentials is in proportion to the degree of depression. The variations in potentials are demonstrable on the electroencephalograph. During ether anesthesia, seven typical wave and voltage patterns are discernible in descent from consciousness to overdosage. The pattern is different for each drug. The

Figure 4. Changes (EEG) in electrical activity of the cerebral cortex during ether anesthesia. Seven levels of activity are consistently apparent. As anesthesia deepens the normal fast rhythm is converted to a slower one with increased voltage. Then periods of of activity are ss of

electroencephalogram may be used to guide the anesthetist in determining depth of anesthesia. Variations in activity caused by nonvolatile drugs and combinations of volatile and nonvolatile drugs may be detected by the electroencephalograph. There are, however, pitfalls which may befall one in the use of the electroencephalograph for determining depth of anesthesia. Artifacts, technical difficulties with the apparatus, skill in interpretation of the record and the lag between the time of establishment of the central and of the circulatory effects of the drug limit the usefulness of the encephalogram for routine purposes (Fig. 4).

ABSORPTION AND ELIMINATION OF ANESTHETICS

The absorption and elimination of volatile anesthetics are influenced by the following factors: (1) the tension of concentration in the inspired mixture, (2) the tidal exchange, (3) the minute volume exchange, (4) the functional residual air volume, (5) the solubility coefficient of the drug in blood, (6) the rate of diffusion through the alveolar membrane, (7) the minute volume blood flow through the lungs, (8) the blood flow through the tissues and (9) solubility in the tissues.

A pressure gradient is established from the inspired gases to the blood and thence to the cells. Obviously, the higher the gas tension in the blood, the greater the pressure gradient between it and the cells and the more rapid the saturation of the tissues. An adequate tidal exchange is necessary to allow proper mixing of the gas or vapor with

Figure 3. Closed or rebreathing technique. The closed type apparatus consists of a mask (A) and a rubber breathing bag of 4- or 5-liter capacity (C). A canister (B) containing soda lime is interposed between the mask and breathing bag. In the circle filter the gases are conducted through the canisters by corrugated tubes. Valves at the inlet and outlet of the canister permit a unidirectional flow. Gases and vapors (D) are admitted through an inlet as required.

volatile drugs are more labile and more pronounced. Presumably, this is due to the inertness of volatile drugs. The intracellular concentrations are closely correlated with blood concentrations. Variations in blood concentrations are quickly reflected in the cellular concentration. This does not appear to be the case with nonvolatile drugs.

SIGNS OF ANESTHESIA

Anesthetic drugs affect all physiologic systems to some degree. However, the changes in the nervous system, respiratory system and circulatory system are the most apparent. These three systems are under the constant surveillance of the anesthetist. The character, rate and depth of respiration, the pulse and blood pressure, the reflex changes and the variations in muscle tone are all observed closely.

Four stages of anesthesia are recognized in administering volatile drugs. One stage

merges into the next as the cellular concentrations increase. There is no abrupt line of demarcation between stages.

In stage I, referred to as the *stage of analgesia*, the patient remains conscious but is unable to perceive painful stimuli. Reflexes remain active and the subject attempts to withdraw from the noxious stimuli, even though he does not interpret them as pain. The sensorium remains clear and the subject is aware of his surroundings. This stage is of limited usefulness because the patient is uncooperative.

Stage II is called the *stage of delirium*. The cerebral cortex is depressed and consciousness is lost. Cortical inhibitions are released as control of various centers is lost. The lower, more primitive centers then exert their influence. This stage is characterized by exaggerated reflexes, increased muscle tone, irregular respiration, incoordination, struggling and disorientation. Stimulation of any sort aggravates these undesirable manifestations. Excitement is frequent and signs of sympathetic stimulation are present. This stage is not only of no value, but is one which is avoided and transcended as soon as possible. Fear and apprehension must be allayed and all manipulations and external stimulation held in abeyance until this stage has been passed.

Stage III is the *stage of surgical anesthesia*. Anesthesia is completely established and superficial reflexes are abolished. Deep reflexes and those associated with vital functions remain active. Voluntary movements are absent. Tapping the eyelid no longer evokes the so-called lid reflex. The lid reflex must not be confused with the corneal reflex commonly employed by physiologists as a guide to depth of anesthesia in laboratory animals. The corneal reflex is objectionable as a guide for depth of anesthesia because ulcers result from repeated touching of the cornea. The medullary centers remain active. Respiration is automatic, rhythmical and resembles that noted in normal sleep because cortical and subcortical influences are abolished and it is under sole control of the respiratory centers. Pulse and blood pressure, which are usually elevated in stage II, return to preanesthetic levels. Stage III, since it is broad, is subdivided into sub-stages called planes. Stages are indicated by roman numerals; planes by arabic numerals. In the first plane there is no loss of muscle tone. Ocular movements continue when the lids are retracted and light enters the pupil. These ocular movements disappear in plane

ties are due to asphyxia. As is the case with nitrous oxide, narcotics, basal narcotics, ether, vinyl ether, chloroform, Fluothane or trichlorethylene is used as a fortifying agent. Alone, it is suitable for operations requiring pain relief without muscle relaxation. Ethylene is nonirritating to the respiratory tract and, like nitrous oxide, causes no significant physiologic disturbances if adequate oxygenation is maintained. It is used for induction of ether anesthesia. The chief objection is that it is flammable. The technique of administration is the same as that used for nitrous oxide. It is somewhat more potent than nitrous oxide in comparable circumstances.

Cyclopropane. Cyclopropane (trimethylene) is a stable, flammable, pleasant-smelling, easily inhaled, nonirritating, gaseous hydrocarbon. Induction of anesthesia is rapid, requiring three or four minutes. Most of the gas, irrespective of the length of operation, is eliminated within ten minutes. Recovery of reflex activity occurs promptly in the operating room. All stages are traversed. When overdosage occurs, respiratory failure precedes circulatory failure. Muscle relaxation adequate for abdominal surgery may be obtained without the use of adjuncts if one chooses. Muscle relaxants, such as curare and the synthetic relaxants, permit use of the upper planes of anesthesia. Cyclopropane is more potent than ethylene and nitrous oxide. A tension of 150 to 175 mm. Hg (20 to 25 per cent) in the alveoli is necessary for surgical anesthesia. Respiratory failure results when the tension is about 300 mm. Hg (40 per cent). The margin of safety, therefore, is wide. Anoxia is no problem because 20 per cent or more oxygen may be used at all times. The closed system with total rebreathing is used to administer the gas since it is highly potent and nitrogen need not be eliminated from the system. This is an advantage in view of the high cost and flammability. Anesthesia may be lightened and deepened quickly and at will. This is a distinct advantage in management of poor surgical risks.

Metabolic processes are not significantly disturbed. A slight insignificant elevation of blood glucose occurs, but there is no effect on the carbon dioxide combining power, liver or renal function.

Respiration is depressed, as a rule. The minute volume exchange is reduced, but in spite of this the arterial and venous blood are normally saturated with oxygen. Respiratory acidosis results from carbon dioxide

retention due to this hypoventilation. The most objectionable feature of the drug is the increase in cardiac irritability which causes arrhythmias. These may be ventricular in origin. Ventricular fibrillation may occur if epinephrine is used in conjunction with cyclopropane, because both drugs increase cardiac irritability. Myocardial depression does not occur and cardiac output is decreased only during deep anesthesia. An elevation in blood pressure is often noted during operation which is due to carbon dioxide retention. Postanesthetic nausea and vomiting are less frequent than with ether, but they do occur. At the conclusion of anesthesia, hypotension is sometimes noted which is associated with the respiratory acidosis. At times excessive oozing of blood in the wound occurs. This is due to the elevation in blood pressure and local peripheral vascular dilatation. Bleeding and clotting times are not disturbed.

Vinyl Ether. Vinyl ether (Vinethene) is a highly volatile, flammable liquid which boils at room temperature (28° C.). The vapor is nonirritating, easily inhaled and quickly produces surgical anesthesia. The drug is the unsaturated counterpart of ethyl ether. It is less stable than ether. Approximately 30 to 40 mm. Hg (4 per cent) are necessary in the alveoli for anesthesia; 60 mm. Hg (8 per cent) for respiratory failure. The drug is used as an induction agent for ether anesthesia by the open mask technique and for analgesia for minor surgical procedures. It is also used as a complementary agent to fortify nitrous oxide or ethylene. Vinyl ether is administered by the open drop method in short surgical procedures or in combination with nitrous oxide by the semiclosed method. The closed method is not satisfactory because difficulty is encountered in maintaining an even plane of anesthesia. Even though stage IV can be attained, relaxation is not adequate for major surgery. Induction and recovery are rapid (two to three minutes) and pleasant. Postanesthetic nausea and vomiting are infrequent. Vinyl ether is not chemically stable unless an inhibitor is added and the drug is protected from light, heat and air.

No clinically significant physiologic and metabolic disturbances occur during anesthesia. Hepatic or renal damage does not occur unless this agent is administered repeatedly or if administration is accompanied by anoxia. Vinyl ether is not used for procedures of over thirty minutes, or for those requiring muscle relaxation. The drug is not

the functional residual air. The functional residual air volume is important because it represents the total gas volume which comes into contact with the alveoli and which mixes with tidal air. When the functional residual air volume and the tidal volume are about the same, the changes in alveolar concentration with each respiration are abrupt. This situation is encountered in children. A momentary increase or decrease in concentration is immediately reflected in the blood level and anesthesia lightens or deepens. If the functional residual air volume increases out of proportion to the tidal exchange, mixing does not occur. Saturation and desaturation are impaired and take more than the usual time. An increase in minute volume exchange facilitates tissue saturation by increasing the total quantity of drug carried to the lungs.

The degree of depression depends upon the concentration of the drug in the brain. This in turn depends upon the alveolar tension. An equilibrium is usually established between the tension in the brain and the arterial blood before it is in the rest of the mass of body tissue. The passage of the drug from the blood to the brain is influenced by the cerebral blood flow, the cerebral vascular resistance and the ease of penetration of the drug through the blood brain barrier. Once equilibrium is established between the alveolar air and the brain, anesthesia would be maintained at a given level were it not for the absorption of the drug by the other tissues. This necessitates the intermittent addition of drug to the inhaled mixture to replace the amount being drawn from the arterial blood by the muscles, fat and other non-nervous tissue.

Volatile anesthetics diffuse through the alveolar membrane in the same manner as do other gases and vapors. The drug does not alter the membrane, otherwise it would be unsuitable clinically. Volatile anesthetics are often referred to as irritating, the inference being that the alveolar membrane is in some way injured. This is not so. Most volatile drugs, particularly ether, stimulate the vagal nerve endings in the pulmonary tissues and cause exaggerated breathing. Also the mucous glands in the respiratory tract are stimulated and excessive secretions accumulate. Both responses are mistakenly interpreted as "irritation."

INHALATION ANESTHETICS

Nitrous Oxide. Nitrous oxide, often referred to as "gas," is a nonirritating, sweet-

smelling, nonflammable gas of mild narcotic potency. It rarely yields anesthesia deeper than the first plane. The alveolar tension for surgical anesthesia varies between 625 and 650 mm. Hg (80 to 85 per cent). Induction and recovery are rapid—approximately three minutes. Nitrous oxide is not suitable for operations requiring profound anesthesia or muscle relaxation. Its effectiveness is increased when combined with morphine or other narcotics, thiopental, ether, vinyl ether, chloroform, Fluothane, trichlorethylene or the muscle relaxants. Unless thus fortified, suboxygenation invariably occurs. Overdosage does not occur if the gas is administered at atmospheric pressure with more than 20 per cent oxygen.

Nitrous oxide is an effective analgesic. An alveolar tension of 365 to 380 mm Hg (35 to 50 per cent) causes a high degree of analgesia. Its use as an analgesic is limited because little surgery can be performed effectively with analgesia. Nitrous oxide is used as an induction agent for ether anesthesia and in combination with basal narcotics in situations in which cautery, endotherms, endoscopes or other equipment which may be a fire hazard are required. It is also used for analgesia for obstetric or dental surgery. Nitrous oxide is administered by means of semiclosed inhalers in order to permit the elimination and replacement of nitrogen from the blood and tissues by the gas. Without anoxia, the drug disrupts none of the important vital functions. Desirable features are that it is nonflammable, nonirritating to the respiratory tract, relatively inexpensive and rapidly absorbed and eliminated. Postanesthetic nausea and emesis are infrequent. There is no justification in using the drug if anesthesia cannot be obtained without anoxia. Most fatalities caused by nitrous oxide are due to asphyxia. When administered in nonasphyxial concentrations, there are no contraindications to its use.

Ethylene. Ethylene is a nonirritating, flammable, gaseous hydrocarbon with an ethereal odor and a mild narcotic potency. Pharmacologically, it is similar to nitrous oxide. Anesthesia is characterized by rapid induction and recovery. The depth attained is rarely lower than plane 1 or the upper limits of plane 2. An alveolar tension of approximately 540 mm. Hg (75 per cent) is necessary for anesthesia. Well premedicated patients require less. As is the case with nitrous oxide, respiratory failure occurs only when anesthesia is complicated by anoxia. Fatali-

trations and in situations in which a fire hazard exists. Surgical anesthesia results with alveolar tensions of 5 to 8 mm. Hg (1.5 per cent) and respiratory failure with 15 to 16 mm. Hg (2 per cent). The margin of safety is narrow. Induction of anesthesia is rapid. Preliminary agents, such as nitrous oxide or ethylene, are not required. Chloroform has been used in tropical areas because it is less volatile than are other drugs. As in the case of ether, simple equipment (open masks) may be used for administration. Exaggerated breathing results but to a lesser extent than that caused by ether. The extreme potency and low partial pressure necessary for anesthesia permit the use of air as a source of oxygen and as a vehicle in open methods.

Chloroform exerts a dual effect on the heart by depressing the myocardium and increasing irritability of the conductive tissues. Cardiac output is reduced as anesthesia deepens. Ventricular fibrillation occurs if epinephrine is given during chloroform anesthesia. At the point of respiratory failure, myocardial depression may proceed to asystole and one is then confronted by two emergencies in such an event. Liver function is depressed more with chloroform than with any other volatile agent. Besides, hepatitis may occur postoperatively from a direct toxic effect on liver cells. Elevation of blood sugar, alteration in acid-base balance, and dehydration occur. The prothrombin time is prolonged. Phosgene forms when vapors are exposed to flames or cautery. Postanesthetic nausea and vomiting are frequent. Diseases of the heart, hypertension, hypotension, liver and renal derangement and diseases of the respiratory tract are contraindications to the use of chloroform.

Fluothane. Fluothane is a two carbon compound having three fluorine atoms on one carbon and a bromine, chlorine and hydrogen atom on the other. The compound is thus a halogenated hydrocarbon. Fluothane is the most potent inhalation anesthetic known. Interest in the derivative was aroused by its potency and nonflammable and relatively nonirritating qualities. The odor resembles that of chloroform, though it is less pungent. Like related halogenated hydrocarbons, it manifests cardiotoxic and hepatotoxic qualities. Immediately after induction, hypotension develops which is due to a combination of several factors, among which are a decrease in cardiac output and varying degrees of ganglionic blocking ac-

tion. The myocardium is depressed and cardiac irritability is enhanced, particularly during deep anesthesia. Spontaneous arrhythmias are common when anesthesia is deep. Ventricular tachycardia and fibrillation occur when the drug is used simultaneously with epinephrine and closely allied amines. The drug is used largely in combination with nitrous oxide, since it is only in this manner that an unvarying concentration may be maintained. Induction is rapid (2 to 3 minutes). Recovery, likewise, is rapid. With nitrous oxide, concentrations varying from 0.1 to 0.5 per cent are adequate for surgical anesthesia. Liver function is depressed but not to the extent it is with chloroform.

Trichlorethylene. Trichlorethylene (Trilene) is a colorless, heavy liquid. It is an unsaturated halogenated hydrocarbon-ethylene with three hydrogen atoms replaced by chlorine. The odor resembles that of chloroform. Waxoline blue is added to avoid mistaking one for the other in localities where both drugs are used. Oxidation converts the drug to phosgene. The open or semiclosed techniques are used for its administration. The closed system cannot be used because soda lime converts the drug to dichloroethylene which is neurotoxic. Mixtures of trichlorethylene and oxygen (10 per cent) are combustible but in the concentration used for surgical anesthesia are not flammable.

Alveolar tensions of 25 to 30 mm. Hg (4 per cent) are anesthetic. The tension necessary for respiratory failure has not been established. Respiratory failure precedes circulatory failure when overdosage occurs. Tensions of 2 to 8 mm. Hg (0.25 to 1.0 per cent) are analgesic. Most of the drug is exhaled unchanged, but some is transformed to trichloroacetic acid by the liver and excreted into the urine.

Induction is slow and resembles that of ether. Analgesic concentrations are not irritating but anesthetic concentrations cause excessive salivation and secretion of mucus. Trichlorethylene causes tachypnea by stimulating the vagus nerve endings. The respiratory rate may exceed 60 per minute at times. Trichlorethylene depresses the myocardium and increases cardiac irritability. It is used for analgesia but is not recommended for surgical anesthesia. Besides being toxic, it produces relaxation of skeletal muscle that is not adequate for major surgery. It is important to differentiate between analgesia and anesthesia. Inhalers are available for self-administration of the drug to provide

used when hepatic or renal disease exists. Excess secretions may help disseminate and thereby aggravate an acute upper respiratory infection.

Ether. When doubt exists concerning selection of an anesthetic, ether, in spite of alleged shortcomings, still remains the safe and reliable choice. Ethyl ether is a volatile, flammable liquid whose vapor possesses marked narcotic potency. The vapor is heavier than air, pungent and induces coughing when inhaled in anesthetic concentrations without previous acclimatization. Ether is suitable for major surgery requiring muscular relaxation. It possesses a wide margin of safety. The alveolar tension necessary for surgical anesthesia is approximately 30 mm Hg (4 per cent), for respiratory failure 60 mm Hg (8 per cent). This wide margin of safety is one of the desirable features of ether.

Ether is administered by open masks using air as a vehicle, by the insufflation technique using air or oxygen as a vehicle, by the semi-open inhaler with nitrous oxide, or by means of closed inhalers with oxygen. The induction period is unusually long because of the pungent irritating effects and because of the marked capacity of the body for the drug. Ether, compared to other volatile anesthetics, is water soluble and the body is capable of absorbing a considerable quantity. Besides, it has a high blood-air coefficient (15:1) so that partition between blood and alveolar air is slow. The elimination requires many hours on this account. The time for complete elimination thus varies with the duration and depth of anesthesia. To simplify and shorten induction, a non-irritating, rapid-acting drug, referred to as the induction agent, is first used. The drug used for induction is nitrous oxide, ethylene, cyclopropane, vinyl ether, chloroform or ethyl chloride. As soon as anesthesia is induced with the preliminary agent, the anesthetic concentration of ether is delivered. This can be done more rapidly than would be possible if the ether were given directly. The first and second stages thereby are shortened.

Ether is relatively inexpensive, is chemically stable, easily preserved and is administered by simple apparatus when necessary. The assertion that the open drop technique is the best for ether is fallacious. In an emergency, it is the safest technique to use by inexperienced individuals. The closed methods are far more satisfactory. Air may be used as a diluent and as the source of

oxygen because the tension required for anesthesia is low. At ordinary levels of anesthesia, ether exerts few deleterious effects upon the circulatory system. Respiratory movements are exaggerated owing to stimulation of the alveolar vagal nerve endings by the vapor. Nausea and vomiting are common in the postanesthetic period. Liver function, acid-base balance and carbohydrate metabolism are temporarily disturbed. Acidosis from any cause is enhanced by ether anesthesia. Ether should be avoided in an acute respiratory infection. It is contraindicated in syndromes of the brain accompanied by increased intracranial pressure because it often causes a further increase in pressure.

Ethyl Chloride. Ethyl chloride is a highly volatile, flammable liquid whose vapor is pleasant smelling, easily inhaled and produces surgical anesthesia. Chemically it is a stable halogenated hydrocarbon. Analgesia results when the alveolar tension is 15 to 20 mm Hg (2 to 3 per cent), anesthesia at 30 to 35 mm Hg. Induction and recovery are rapid, usually requiring two to three minutes. It is used as an induction agent to shorten the first and second stage of ether anesthesia administered by the open mask techniques and for anesthesia and analgesia in operations for minor surgical procedures of not more than several minutes' duration. Ethyl chloride ordinarily is administered by the open drop method. Air acts as both the vehicle and as a source of oxygen.

Ethyl chloride does not cause respiratory depression. Cardiac arrest may result from direct depression of the myocardium. Besides, it increases cardiac irritability and causes serious arrhythmias. Ventricular fibrillation may occur early in anesthesia. Asystole may occur before medullary paralysis. For this reason, the use of the drug is not advised for any procedure. Anesthesia at times is accompanied by stridor or muscle rigidity. The depth of anesthesia is difficult to maintain at a constant level because of the high volatility. Postanesthetic nausea and vomiting are uncommon.

Chloroform. Chloroform (trichloromethane) is a colorless, volatile liquid whose vapor is sweet smelling, easily inhaled and nonflammable. All types of surgery requiring muscle relaxation may be performed with chloroform anesthesia. Chloroform is unsafe because it is cardiotoxic and hepatotoxic. It has been used as an induction agent for shortening stage II of ether anesthesia, as an analgesic for obstetrics in dilute concen-

analgesia for minor procedures. Trichloroethylene is used to fortify nitrous oxide.

ENDOTRACHEAL ANESTHESIA

Endotracheal anesthesia consists of introducing a catheter into the trachea through the mouth or nose and conducting the gases and vapors directly from the apparatus to the lungs. Actually, the catheter extends or prolongs the trachea to the lips or nares. During general anesthesia, the muscles of the neck, tongue, pharynx and jaw relax and the tongue sags backward. As they do so, the epiglottis swings posteriorly and occludes the pathway into the trachea and respiratory obstruction results. A properly placed catheter provides an unimpeded airway. In addition, it permits the anesthetist to employ positive pressure and artificial respiration when indicated.

A catheter of smaller diameter may be passed into the tracheal catheter to aspirate secretions. The endotracheal catheter prevents laryngeal spasm by keeping the cords abducted. Certain surgical manipulations such as incising the periosteum, making traction upon the organs in the abdomen and thorax, dilating the rectum or stimulating the perineal structures excites reflexes which cause laryngeal spasm. The catheter prevents the spasm. A properly introduced endotracheal catheter prevents aspiration of vomitus. The catheter assures an airway for patients undergoing surgery in the prone or lateral positions as in the cases of operations upon the vertebral column, back and head or thorax. In surgery of the mouth, pharynx and larynx an endotracheal tube allows the anesthetist to be out of the operative field and still have control of the airway. Endotracheal anesthesia is necessary for obese individuals and others in whom an open airway is maintained with difficulty.

The catheter is introduced by direct laryngoscopy, that is, the larynx is visualized directly with a laryngoscope. When the catheter is introduced through the mouth, the procedure is called *oral endotracheal intubation*. In nasal intubations, the catheter is introduced through the nostril which is most patent and free from obstruction. The curvature of the catheter and the anatomic position of the larynx favor passage into the trachea without laryngoscopy. This procedure is called *blind nasal intubation*. When the catheter cannot be passed blindly, the larynx is exposed with the laryngoscope and the tube is introduced under direct vision with a forceps.

Figure 5 Closed oral endotracheal anesthesia is accomplished by connecting an intratracheal catheter (A) equipped with an inflatable cuff to an adaptor which replaces the mask of a circle filter. An entirely closed system is obtained. Anesthesia is conducted in the same manner as it would be if a mask were used. (From Adnam. *Techniques and Procedures of Anesthesia*. Courtesy Charles C Thomas, Publisher.)

If, in the oral technique, the mask is replaced over the mouth after intubation the technique is called *open oral endotracheal anesthesia*. If the catheter is introduced nasally and the mask is replaced over the nose and mouth, the technique is known as *open nasal endotracheal intubation*. The catheter may be connected directly to a closed or semiclosed inhaler. When this is done, the technique is called *closed endotracheal anesthesia* (Fig. 5). Sometimes an inflatable cuff or a gauze pack is used to seal the space between the wall of the trachea and the catheter and provide a leak-proof closed system. Catheters are made of rubber, plastic or metal. Wire coils are often incorporated in the wall of rubber catheters to prevent kinking.

Endobronchial anesthesia consists of introducing a longer, special catheter into the bronchi. Endobronchial catheterization is usually employed for partial or complete pneumonectomy for suppurative diseases of the lungs to prevent secretions from passing from the diseased to the healthy lung. Catheters used for differential bronchspirometry are also suitable in these circumstances. Each division passes into the right and left bronchus respectively. Anesthesia is conducted and aspiration accomplished in each lung separately.

For intubation, general anesthesia is induced in the usual manner with cyclopropane, ether or other drug until the neck and jaw muscles relax. The larynx is then exposed and the catheter inserted. A muscle

relavant facilitates the intubation. Unless performed by skilled operators, considerable trauma may result to the pharynx, larynx and trachea which may be followed by serious consequences. The advantages of endotracheal anesthesia outweigh most disadvantages. Difficulties encountered, as a rule, are due to poor technique.

In certain surgical procedures, apnea is deliberately induced and respiration is maintained artificially to provide a quiet operative field. Such operating conditions facilitate intrathoracic and upper abdominal operations. Ventilation, referred to as controlled respiration, is maintained by rhythmic compression of the breathing bag of the anesthetic apparatus approximately twenty times per minute. Apnea is induced by using a drug which depresses the respiratory center, usually a nonvolatile drug and cyclopropane. The overdistention of the alveoli to excite the Hering-Breuer reflex to inhibit inspiration and hypocapnia caused by hyperventilation also contributes to the development of the apnea. Some anesthesiologists cause the apnea by curarizing the patient to the point of complete muscle paralysis. The effect of increased pressure on the airway

With the exception of ether, most anesthetic drugs cause hypoventilation. Ether causes exaggerated breathing and in increased minute volume exchange. Both oxygenation and carbon dioxide elimination are adequate. With other drugs oxygenation may be adequate, but carbon dioxide elimination is not. In order to prevent respiratory acidosis, the minute volume exchange must be augmented by compression of the breathing bag manually. This is referred to as assisted respiration. Automatic ventilating machines are available which either assist patients who, though making respiratory efforts, do not have an adequate minute volume exchange or breathe artificially for patients who are apneic. These devices are useful for specialized surgical procedures (intrathoracic) but are superfluous for routine use.

BASAL NARCOTICS

Ethyl Alcohol. Ethyl alcohol is not satisfactory for surgical anesthesia because it does not completely abolish the reflexes and it possesses a narrow margin of safety. The concentration necessary for anesthesia, in a

surgical sense, approximates that which causes medullary depression. The systemic effects are the same regardless of the route of administration. Ethyl alcohol is administered intravenously (5 per cent with 5 per cent dextrose in distilled water) for analgesia postoperatively or for sedation preliminary to anesthesia for addicts or patients who cannot be given narcotics for other reasons.

Paraldehyde. Paraldehyde is a colorless, mobile liquid possessing a pungent odor which appears to cling to surrounding objects for days. The drug is a polymer of acetaldehyde. It is used as a hypnotic for alcohol addicts and mentally disturbed patients or as a basal narcotic preliminary to surgery. Its use as an amnesic agent for obstetrics has also been described but is not advised. Paraldehyde possesses anticonvulsant properties. The drug is administered rectally or intravenously. Like other non-volatile substances, it lacks analgesic properties and the ability to abolish reflexes completely. It is characterized by a variability of action. The drug causes irritation of the mucosa of the mouth, stomach and rectum. Basal narcotic doses disturb metabolic processes. An elevation in blood sugar and lowering of carbon dioxide combining power are frequently observed. Some of the drug is exhaled through the lungs, but the bulk of it is detoxified by the liver. Paraldehyde is not used when pulmonary diseases or hepatic or renal insufficiency exists.

Tribromethanol (Avertin). Tribromethanol, a halogenated derivative of ethyl alcohol, is a white crystalline substance with an ethereal odor. The drug is poorly soluble in water but very soluble in amylene hydrate (tertiary amyl alcohol). The latter is used as a vehicle to prepare a solution used in clinical medicine known as Avertin fluid. One cubic centimeter of Avertin fluid contains 1000 mg. of the drug and 500 mg. of the solvent. A 3 per cent solution in water (27 to 36 mg. per pound of body weight) is administered rectally forty-five minutes before induction of anesthesia. The drug is ineffective orally, its action intravenously is variable. Following rectal administration, a deep stage of hypnosis accompanied by amnesia develops within five minutes. Reflexes are not completely abolished, however, and surgery cannot be performed without a supplemental anesthetic such as a nerve block, cyclopropane, nitrous oxide or ether. The drug is conjugated with glycuronic acid by the liver and the product is

excreted by the kidneys. Avertin is used to control convulsions and other hyperirritable states of the nervous system such as are encountered in tetanus, rabies or drug reactions. Recovery from hypnosis is gradual over a period of several hours. Prolonged amnesia results. Avertin is administered at the bedside to allay apprehension preoperatively. It thus eliminates excitement during induction of inhalation anesthesia. Tribromethanol is nonirritating to the respiratory tract but does depress respiration. Postoperative nausea and vomiting are minimized and the amount of supplemental anesthetic necessary is reduced. It is uncontrollable, however, once a dose is administered it cannot be retrieved. The exact dose is difficult to estimate owing to variations in susceptibility of the individual and absorption from the rectum. Hypotension due to depression of the vasomotor center is frequently observed. Repeated doses result in cumulative effects. Laryngeal and pharyngeal reflexes are partly obtunded and are reactivated by stimulation. Constant attendance of the patient is required from the moment the drug is administered until narcosis has receded. Proctitis and colitis may result from use of deteriorated solutions. The drug is not stable and deteriorates if solutions are heated or allowed to stand. Hepatic and renal diseases, "toxemia," sepsis, acidosis, shock or other forms of hypotension, dehydration, low metabolic rate, chronic pulmonary disease, disease of the gastrointestinal tract, amnesia and chronic alcohol addiction are contraindications to the use of the drug.

Barbiturates. One of the most useful groups of drugs in medicine is the barbiturates. The barbiturates possess no significant analgesic properties and cannot, therefore, be used alone for pain relief. Barbiturates are placed into four groups, namely, the long acting, the intermediate acting, the short acting and the ultra-short acting. The long and intermediate acting derivatives are used for sedation. The short acting and ultra-short acting are used in conjunction with surgical anesthesia as basal narcotics. Barbiturates are usually given intravenously when used for basal narcosis. The rectal route is used for children. The ultra-short acting derivatives are more potent than the short acting. All barbiturates manifest a latent period from the moment of injection until the peak effect is attained. The latent period is briefest and the peak effect most intense with the ultra-short acting drug, *Thiopental* (*Pentothal*), *thiosecobarbital*

(*Surital*) and *hexobarbital* (*Evipal*) are the most important currently used derivatives. A dilute solution of any of these injected intravenously causes unconsciousness within thirty-five or forty seconds. These compounds pass quickly from the blood and are stored in the lipid and other tissues. Recovery occurs when the blood level falls. Fractional doses are administered at frequent intervals in order to maintain basal narcosis. In due time enough of the drug accumulates in the adipose tissue to maintain a sustained depressed state. Reflex activity is not completely abolished during barbiturate narcosis. The patient does not respond, however, unless stimulated. Painful stimuli often cause the patient to become partly roused into a delirious, unruly state. It is customary in present-day practice to combine barbiturates with an analgesic, usually nitrous oxide. Neither the barbiturate nor the nitrous oxide yields satisfactory muscle relaxation. This is obtained by adding a muscle relaxant.

Barbiturates cause depression of the medullary centers. Hypotension, due to depression of the vasomotor center, is not uncommon after intravenous administration. A cumulative action invariably occurs when fractional doses are administered over a long time. The barbiturates are, therefore, used at the beginning of anesthesia to facilitate induction or for short procedures. The laryngeal, pharyngeal and bronchial reflexes remain active. In fact, the thiobarbiturates enhance the activity of these reflexes and intense bronchial and laryngeal spasms are initiated by stimulation of the upper respiratory passages. Mucus, blood, or surgical manipulation in the respiratory tract may give rise to serious difficulties. The effective dose varies with the susceptibility of the individual. As a rule, 1.0 gm. is the average dose for an adult. Recovery after short procedures is prompt. Detoxification occurs in the liver. The rate depends on the total amount injected and the metabolic state of the patient.

Aqueous solutions of salts of barbiturates are alkaline. Phlebitis and thrombosis may occur after intravenous administration. Induction of basal narcosis is rapid and pleasant with intravenous barbiturates. Secretions are absent in contradistinction to the volatile anesthetic drugs. The barbiturates are the only agents which may be used in areas where a fire hazard exists, particularly when the anesthetic is to be combined with nitrous oxide. Nausea and vomiting are uncommon

following the use of barbiturates. The ultra-short acting barbiturates are not desirable for patients at the extremes of age, in hypotensive states (shock) or for those who have any of the anemias or any disease of the respiratory tract characterized by dyspnea, hypoventilation, excessive secretions due to suppuration, or reduction in pulmonary function.

NARCOTICS

The narcotics are nonvolatile drugs which possess both analgesic and hypnotic properties. Most narcotics induce a psychic response often termed, "a sense of well-being" or "euphoria." Narcotics obtund dull aching types of pain more effectively than the sharp, lancinating types. Unless large doses are used, reflex activity is not abolished. The narcotics, therefore, are suitable only for relieving pain preoperatively or postoperatively or after trauma, but not for producing surgical anesthesia. The feeling of well-being and the air of indifference induced by narcotics make them superior to other drugs for preanesthetic medication. Barbiturates and other hypnotics do not as a rule induce this response and are, therefore, used less frequently for psychic sedation preliminary to surgery.

Until recent years the only useful narcotics were opium derivatives. Synthetic narcotics are now available. Qualitatively, they are similar to opium derivatives, but quantitatively they are different. Meperidine (Demerol), methadone, methyl morphinan (Dromoran), anilerdine (Leritine) and alpha-prodine (Nisentil) are suitable analgesics but less effective as preanesthetic medicaments. The opium alkaloids are derived from phenathrene. The most important of these, of course, is morphine. Modifications of the morphine molecule yield codeine and dihydromorphinone (Dilaudid). Tolerance and habituation quickly result when narcotics are administered repeatedly for a time. After several weeks physical dependence (addiction) develops. In addition, the drug is required to maintain necessary cellular functions and withdrawal results in the abstinence syndrome, the symptoms of which suggest an organic disease.

MUSCLE RELAXANTS

Muscle relaxants are nonanesthetic substances used as adjuncts to anesthesia. They act by interfering with the transmission of impulses from peripheral nerves to striated muscle. They do not block the nerve or

depress the muscle fibers. They are non-hypnotic and nonanalgesic. Two types are recognized: those which prevent acetylcholine from acting at the receptor organ of the muscle fiber and those which cause a persistent depolarization of the membrane at the receptor substance.

Curare was, at one time, the most widely used muscle relaxant. The active principle in curare is the alkaloid tubocurarine. Synthetic substances are now used, the most important of which are decamethonium and succinylcholine. Curare and tubocurarine inhibit acetylcholine; decamethonium and succinylcholine cause persistent depolarization. Succinylcholine is rapidly hydrolyzed by cholinesterase. Its action, therefore, is fleeting and sustained relaxation can only be obtained by continuous infusion.

When relaxation is desired, the drug is administered intravenously. Complete muscle paralysis may be secured during which respiration must be sustained artificially. By controlling dosage, paresis of large muscles without apnea results. The action of curare lasts fifteen to twenty minutes after which time the dose must be repeated. The combination of nitrous oxide, a muscle relaxant and basal narcosis, using an ultra-short acting barbiturate (thiopental), is widely used.

The most widely used and the safest of the muscle relaxants is succinylcholine. Its transient and fleeting action and ready destruction in the body make it controllable. Difficulties do arise, however, after prolonged use or after the use of excessive quantities. The most vexing of these are the prolonged apneas lasting many hours. These are seen when the drug is administered by the continuous infusion technique and given to the point of complete paralysis which necessitates controlled respiration. Difficulties are uncommon when the drug is used in intermittent fractional doses.

LOCAL AND REGIONAL ANESTHESIA

Regional, or conduction, anesthesia is employed when one wishes to obviate the risks, disadvantages and discomforts of general anesthesia. Regional anesthesia is subdivided into: (1) spinal block in which the drug is introduced in the subarachnoid space and exerts its effect on the spinal nerve roots, (2) peridural block in which the drug is applied in the peridural space, (3) nerve block in which the drug is applied directly to a nerve, (4) field block in which a group of nerves is blocked as each branches from a main trunk, (5) infiltration, in which the

excreted by the kidneys. Avertin is used to control convulsions and other hyperirritable states of the nervous system such as are encountered in tetanus, rabies or drug reactions. Recovery from hypnosis is gradual over a period of several hours. Prolonged amnesia results. Avertin is administered at the bedside to allay apprehension preoperatively. It thus eliminates excitement during induction of inhalation anesthesia. Tribromethanol is nonirritating to the respiratory tract but does depress respiration. Postoperative nausea and vomiting are minimized and the amount of supplemental anesthetic necessary is reduced. It is uncontrollable, however, once a dose is administered it cannot be retrieved. The exact dose is difficult to estimate owing to variations in susceptibility of the individual and absorption from the rectum. Hypotension due to depression of the vasomotor center is frequently observed. Repeated doses result in cumulative effects. Laryngeal and pharyngeal reflexes are partly obtunded and are reactivated by stimulation. Constant attendance of the patient is required from the moment the drug is administered until narcosis has receded. Proctitis and colitis may result from use of deteriorated solutions. The drug is not stable and deteriorates if solutions are heated or allowed to stand. Hepatic and renal diseases, "toxemia," sepsis, acidosis, shock or other forms of hypotension, dehydration, low metabolic rate, chronic pulmonary disease, disease of the gastrointestinal tract, amnesia and chronic alcohol addiction are contraindications to the use of the drug.

Barbiturates. One of the most useful groups of drugs in medicine is the barbiturates. The barbiturates possess no significant analgesic properties and cannot, therefore, be used alone for pain relief. Barbiturates are placed into four groups; namely, the long acting, the intermediate acting, the short acting and the ultra-short acting. The long and intermediate acting derivatives are used for sedation. The short acting and ultra-short acting are used in conjunction with surgical anesthesia as basal narcotics. Barbiturates are usually given intravenously when used for basal narcosis. The rectal route is used for children. The ultra-short acting derivatives are more potent than the short acting. All barbiturates manifest a latent period from the moment of injection until the peak effect is attained. The latent period is briefest and the peak effect most intense with the ultra-short acting drug. Thiopental (Pentothal), thiosecobarbital

(Surital) and hexobarbital (Evipal) are the most important currently used derivatives. A dilute solution of any of these injected intravenously causes unconsciousness within thirty-five or forty seconds. These compounds pass quickly from the blood and are stored in the lipid and other tissues. Recovery occurs when the blood level falls. Fractional doses are administered at frequent intervals in order to maintain basal narcosis. In due time enough of the drug accumulates in the adipose tissue to maintain a sustained depressed state. Reflex activity is not completely abolished during barbiturate narcosis. The patient does not respond, however, unless stimulated. Painful stimuli often cause the patient to become partly roused into a delirious, unruly state. It is customary in present-day practice to combine barbiturates with an analgesic, usually nitrous oxide. Neither the barbiturate nor the nitrous oxide yields satisfactory muscle relaxation. This is obtained by adding a muscle relaxant.

Barbiturates cause depression of the medullary centers. Hypotension, due to depression of the vasomotor center, is not uncommon after intravenous administration. A cumulative action invariably occurs when fractional doses are administered over a long time. The barbiturates are, therefore, used at the beginning of anesthesia to facilitate induction or for short procedures. The laryngeal, pharyngeal and bronchial reflexes remain active. In fact, the thiobarbiturates enhance the activity of these reflexes and intense bronchial and laryngeal spasms are initiated by stimulation of the upper respiratory passages. Mucus, blood, or surgical manipulation in the respiratory tract may give rise to serious difficulties. The effective dose varies with the susceptibility of the individual. As a rule, 1.0 gm. is the average dose for an adult. Recovery after short procedures is prompt. Detoxification occurs in the liver. The rate depends on the total amount injected and the metabolic state of the patient.

Aqueous solutions of salts of barbiturates are alkaline. Phlebitis and thrombosis may occur after intravenous administration. Induction of basal narcosis is rapid and pleasant with intravenous barbiturates. Secretions are absent in contradistinction to the volatile anesthetic drugs. The barbiturates are the only agents which may be used in areas where a fire hazard exists, particularly when the anesthetic is to be combined with nitrous oxide. Nausea and vomiting are uncommon

used to anesthetize mucous membranes. The duration of action of procaine in a nerve block averages forty-five minutes. Various modifications of procaine are available. One of these, *chloroprocaine* (*Nesacaine*), is equally as potent but less toxic than procaine. It is used for the same purposes and in the same general manner as procaine.

Tetracaine (*Pontocaine*) is more potent and more toxic than procaine. It is second in importance to procaine for surgical anesthesia. One milligram of tetracaine is equivalent to 10 mg. of procaine as regards its anesthetic potency. The duration of action of tetracaine is almost twice that of procaine. It is possible, if epinephrine is added to solutions of tetracaine, to obtain a block lasting from two to four hours. Large nerve trunks are blocked with 0.15 per cent solutions, smaller trunks with 0.10 per cent, and nerve endings (infiltration) by 0.05 per cent to 0.075 per cent solutions. Tetracaine is used extensively for spinal anesthesia.

Symptoms of toxicity following the use of tetracaine are more frequent and serious than those of procaine. Reactions are characterized by syncope and circulatory collapse. As a rule, few if any prodromal symptoms precede or forewarn of impending catastrophe. The use of tetracaine for other than spinal block should be reserved for those experienced in the technique of regional anesthesia.

Piperocaine (*Metycaine*) is closely allied to cocaine chemically, being an ester of benzoic acid. It is similar to procaine in most respects. However, it is somewhat more potent and longer lasting. One and one-half per cent solutions are suitable for blocking large and medium sized nerve trunks. A one per cent solution should be used for smaller nerve trunks and for infiltration.

Lidocaine is a newer anesthetic drug. It is a xylidide (not an ester), but it does possess the general chemical configuration common to other local anesthetics. It has a very brief latent period and produces almost immediate anesthesia and, when infiltrated, it produces an effect lasting one hour without epinephrine and two to three hours with epinephrine. The volumes and strength of solutions recommended are approximately one-half to two-thirds of those for procaine in similar situations. Lidocaine possesses striking ability to diffuse through tissues. Thus, if perchance the needle is introduced some distance from the nerve, an effective block is still obtained because the drug diffuses over a wide area and reaches the

nerve. The incidence of failures is reduced noticeably in comparison to procaine when one adopts the drug. Blocks in which motor effects are partial or absent when procaine is used yield complete flaccidity with lidocaine.

Dibucaine (*Nupercaine*) is approximately fifteen times more potent and toxic than is procaine. Its effect is longer lasting than that of any of the currently used drugs. Nerve blocks may be performed with a 0.075 per cent solution and infiltration with a 0.05 per cent. Sloughs and severe systemic manifestations of toxicity have been reported. The drug is not recommended for infiltration and nerve blocking but is suitable for spinal anesthesia.

Commercially prepared, ready mixed and sterilized solutions of local anesthetic drugs are available in sealed glass ampules or multiple-dose vials. Such preparations are preferred, from the standpoint of safety, stability, asepsis and ease of handling, by the operator to those made up from tablets and powders. Accidents due to the use of concentrated solutions and the possibility of contamination are thus avoided.

When these preparations are not available, the powder may be dissolved in the appropriate solvent and sterilized by autoclaving or boiling. Epinephrine is added at the time the solution is used because it is not stable and cannot be boiled. Solutions as nearly isotonic as possible are used in order to prevent swelling and edema of the tissues during operation and local irritation afterwards. Potent drugs such as tetracaine or dibucaine are dissolved directly in physiologic saline, since the amount necessary for effectiveness is, comparatively speaking, minute and toxicity is not altered. Two per cent procaine must be prepared with 0.45 per cent sodium chloride to be isotonic.

The most efficient vasoconstrictor for local anesthesia is epinephrine. It is never used for patients with cardiovascular disease, peripheral vascular disease, hyperthyroidism or those who have had a sympathectomy. Injections of solutions containing epinephrine into the fingers and toes, particularly when peripheral vascular disease is present, may cause gangrene and slough.

REACTIONS TO LOCAL ANESTHETIC DRUGS

When local anesthetic drug gains access to the blood stream, either by injection or by absorption, a train of symptoms commonly referred to as a "reaction" results. Two types of reactions are recognized: the

tissues at the surgical site are infiltrated so that each individual nerve ending is blocked by disseminating a solution over a wide area and (6) topical, in which the drug is applied on a mucous membrane through which it penetrates and anesthetizes the nerve ending beneath it.

Local Anesthetic Drugs. Numerous drugs are available for conduction anesthesia. In order to be of practical value for blocking or conduction anesthesia, a drug must possess the following qualities. (1) the ability to produce an adequate intensity of anesthesia within several minutes, (2) the capacity to give an effect lasting long enough to permit successful completion of the operation, (3) the inability to cause local irritation immediately after injection or in the postoperative period, (4) the inability to produce local tissue damage or to retard healing, (5) low systemic toxicity and (6) compatibility with vasoconstrictors such as epinephrine and similar drugs. The vasoconstrictors are added to retard absorption, which in turn decreases systemic toxicity and prolongs the effect.

Local anesthetics are basic organic substances which form salts with mineral and organic acids. The majority of injectable drugs are esters. The salts are soluble in water and insoluble in organic solvents. The bases are soluble in organic solvents, oils and vehicles used for ointments, but poorly soluble in water. Alkalis precipitate the basic form from aqueous solutions of salts.

Detoxification of local anesthetics occurs in the liver. The rate varies with the chemical nature of the drug. Some are completely hydrolyzed and the by-products are excreted into the urine. Procaine, for example, is converted to para-aminobenzoic acid and diethylaminoethanol. Others are partly detoxified and partly eliminated unchanged in the urine (cocaine). Still others are almost entirely eliminated unchanged. Greater toxicity is usually associated with slowly eliminated or detoxified drugs.

The effective concentration of a local anesthetic depends upon the size of the nerve fiber. Autonomic and sensory fibers of a mixed nerve are smaller than the motor fibers. If a nerve containing all three components is exposed to a dilute solution of a local anesthetic, a blockade of the sensory and autonomic fibers develops first. Conduction remains in motor components for a variable period. Later, the motor components are affected. This apparent selectivity depends upon the ease of penetration of the

drug into the fibers. Drugs penetrate non-myelinated fibers more easily than myelinated. Penetration into the large nerve trunks, since they have a denser perineural sheath than do the small, occurs at a slower rate. More concentrated solutions are necessary for successful blockade of larger, centrally located nerve trunks than of the smaller, peripherally located branches. The nerve endings in the skin and subcutaneous areas are anesthetized with still more dilute solutions.

When nerve trunks are large, fifteen to twenty minutes may elapse before a satisfactory block is established. This lapse in time, from the moment of injection until the blockade is established, is the sum of the time required for the drug to diffuse through the soft tissues, the time to penetrate and diffuse through the neural sheaths and the time required to diffuse through the perineural membrane and into the nerve fiber. The ease of penetration of a drug through the membrane of a nerve fiber is a physical factor which varies according to the configuration of the molecule of the drug. This latent period, during which nothing seems to be happening, is greater for the longer lasting drugs. Presumably, the longer lasting drug diffuses slowly through the membrane. The outward diffusion, when the concentration of drug in the medium surrounding the nerve fiber is reduced below the equilibrium level, also is slow. These are the reasons for the differences in onset and duration of action of various drugs.

Besides the chemical nature of a drug, duration of action is influenced also by the site of injection, blood supply in the area injected, concentration and ability to detoxify the drug. In the scalp, where the blood supply is excellent, duration is almost half that of the back where it is less abundant.

Procaine is the best known and the safest of the local anesthetics. It is almost universally the agent of choice for local and regional anesthesia. It is rapidly detoxified and eliminated. Reactions are mild when they occur and local damage to tissues is uncommon. The conventional concentrations and volumes for average adults are as follows:

2 per cent—not more than 50 cc. in one hour (1 gm.)
1 per cent—not more than 100 cc. in one hour (1 gm.)
0.5 per cent—not more than 200 cc. in one hour

As a general rule, not more than 1 gm. should be used at any one sitting. Procaine possesses no topical action and cannot be

varying the dosage does not. The extent or level is controlled by dosage, specific gravity of solutions, positioning and rate of injection. The height or level of anesthesia is controlled by using solutions which are heavier or lighter than spinal fluid. Solutions heavier than spinal fluid are referred to as *hyperbaric*; lighter solutions as *hypobaric*; those of the same specific gravity as *isobaric*.

The effects of gravity are utilized in directing the drug to the desired segments. In the head-down, supine position a hypobaric solution migrates caudad, a hyperbaric one gravitates cephalad. In the head-up position the reverse is true. Blocks induced with procaine, intracaine and piperocaine last approximately one hour; with tetracaine and heptylcaine two hours, and with dibucaine three hours. Epinephrine added to the solution increases the duration approximately 60 per cent. Long-lasting anesthesia is obtained by using dibucaine or tetracaine combined with epinephrine by the single injection method or by the continuous spinal technique. In the latter technique, a catheter of small bore is introduced intrathecally and the drug is injected at intervals as often as necessary.

Spinal anesthesia provides muscle relaxation superior to other methods of anesthesia. Surgeons prefer spinal anesthesia for the relaxation it affords.

Certain physiologic disturbances occur during spinal anesthesia of far-reaching importance. In high spinal anesthesia, a blockade of sensory and motor fibers occurs in the sacral, lumbar and lower thoracic segments. However, the autonomic fibers are not all blocked. The sympathetic and parasympathetic fibers in the lower spinal segments are inactivated. In the thoracic segments, the majority of the sympathetic fibers are blocked, but the parasympathetic fibers, since they arise in the cranial nerves, remain intact. This partial denervation of the autonomic nervous system in the upper part of the body causes hypotension, bradycardia, nausea, vomiting, contraction of the bowel and other changes.

Some of the advantages of spinal anesthesia are that it provides excellent muscle relaxation. The reflex arc is interrupted and muscles are completely paralyzed. The block is accompanied by little or no disturbances of metabolic processes if there is no hypotension. Loss of consciousness, excessive secretions, excitement, postanesthetic nausea, somnolence and other disagreeable features of general anesthesia are avoided. Caution

or electrical equipment may be used without fear of explosions. The operator may administer the anesthetic himself.

One disadvantage of spinal anesthesia is that it is noncontrollable. Once anesthesia has been instituted, it cannot be terminated. Its duration, although predictable, is usually uncertain. The operation may outlast anesthesia and supplementary general anesthesia is required which subjects the patient to the hazards of two anesthetics. Failures, due to technical errors, cannot be wholly excluded even in most skilled hands. The motor paralysis at high levels causes respiratory depression from the resulting intercostal and diaphragmatic paresis. Hypotension is common. Paralysis of the muscles and the autonomic denervation contribute to the peripheral circulatory failure. Vasopressor drugs are usually effective in overcoming circulatory failure in healthy subjects, but those with a diseased vascular system do not always respond. Postoperative neurologic complications, though infrequent, are a possibility. The effects of the drug on the nervous tissue, trauma from the needle infections, and the use of contaminated or deteriorated solutions may be causative factors. One objection which is often offered is that the patient remains conscious throughout the operation. All patients are not cooperative and, therefore, are not psychically suited for spinal anesthesia. The vagal pathways from the viscera are not blocked during the time of operation, causing impulses to pass to the medulla. This may initiate veksome retching, nausea and vomiting, particularly when traction is made on the viscera. Impulses pass along the sympathetic chain in a retrograde manner and thence into the cord above the level of the block. The patient experiences pain in the thorax when traction is made upon the viscera.

Because circulatory depression is a prominent and common disturbance in spinal anesthesia, this technique is usually contraindicated when cardiovascular diseases are present. Severe hypertension, disturbances in cardiac rhythm, myocardial disease and cardiac failure are contraindications to spinal anesthesia. Hypotension and hypovolemia from any cause are contraindications to spinal anesthesia for the obvious reason that the vascular bed is increased in size and circulatory depression results. Neurologic diseases, whether degenerative or suppurative, are contraindications to this method of anesthesia. Although no evidence exists that these diseases are aggravated by spinal anes-

depressant or cardiovascular type and the stimulating or convulsive type.

The *depressant* type of reaction is due to circulatory collapse, which is the result of depression of the myocardium, dilatation of the vascular bed or a combination of both. The onset is usually abrupt, sometimes after the use of a minute amount of the drug. Sudden pallor appears followed by syncope and respiratory failure and death. In mild reactions the onset is slower and circulatory failure supervenes gradually. The patient becomes drowsy and passes into a comalike state. Manifestations such as these have been ascribed to idiosyncrasy or sensitivity. It is generally conceded that they are due to overdosage when precautions outlined for using local anesthetics have not been observed. Artificial respiration must be instituted if respiratory failure has occurred. If asystole is suspected, both cardiac massage and artificial respiration must be instituted *simultaneously without delay*.

The *central nervous stimulation* type of reaction is ushered in by apprehension, excitement, disorientation and is then followed by convulsions and other manifestations of intense central nervous stimulation. The circulatory type of reaction occurs less frequently than does the central nervous system type. Pallor, yawning, nausea and vomiting may precede the convulsions. The prodromal signs of the nervous system type are often dismissed as hysteria. The severity and duration of the stimulation depend upon the pharmacologic nature and rapidity of absorption of the drug. The convulsive manifestations may be fleeting and be followed by a paralytic phase if large amounts of the drug are absorbed or injected. The subject is then comatose, completely depressed and in a state of circulatory collapse.

The convulsions are controlled by the intravenous administration of an ultra-short acting barbiturate (thiopental or hexobarbital). If neither of these is available, one of the short acting barbiturates such as secobarbital or pentobarbital may be used. The barbiturate is given intravenously in a quantity sufficient to control the convulsions. The ultra-short acting barbiturates are more suitable for this purpose because they act quickly and are more potent. Barbiturates merely antagonize the stimulating action. They do not hasten detoxification or elimination of local anesthetics, they do not overcome the depressant effect on the circulatory system and they do not antagonize the

paralytic phase of a reaction. They are suitable only to control convulsions.

Fatalities from local anesthetics are most frequent after topical application. The drugs are rapidly absorbed from the mucous membranes of the pharynx, trachea, bronchi and urethra. Blood levels after topical application to the mucous membranes are comparable to those obtained after intravenous administration.

Regional anesthesia should not be attempted without having available an ultra-short acting barbiturate, a vasopressor drug, a syringe and needle and some effective method of administering artificial respiration. The pallor, tachycardia, tremor and excitement caused by epinephrine used with the local anesthetic drug may easily be confused with the prodromal phase of a reaction. However, disorientation, convulsions and coma are uncommon symptoms.

The use of the intradermal wheal to determine sensitivity to local anesthetic drugs is a traditional procedure of doubtful value. Patients presenting a history of developing loss of consciousness or coma, following the injection of small quantities of local anesthetic drugs, should be regarded with suspicion and studied further before a block is attempted.

SPINAL ANESTHESIA

In spinal anesthesia the anterior and posterior roots of the spinal nerves are blocked as they arise from the spinal cord. The neurons and tracts on the surface may be involved, but the descending and ascending tracts deep in the cord substance are not blocked. The extent of the block, referred to as height or level, depends upon the number of spinal roots bathed by the solution. The perineal or saddle area is anesthetized when the sacral segments only are involved. The block is often called *saddle block*. The lower extremities are anesthetized when both the sacral and lower lumbar segments are involved. The block is referred to as *low spinal block*. When the sacral, lumbar and lower thoracic segments are blocked, the block is referred to as *medium*, or simply a *spinal block*. If the drug is forced into the upper thoracic area, the block is called a *high spinal block*.

The spinal cord ends at the level of the second lumbar vertebra. Lumbar puncture is always performed below this site to avoid trauma to the cord. The drug used determines the duration of spinal anesthesia;

injection exists because the epidural space is lined with a plexus of veins.

INFILTRATION ANESTHESIA

As a rule, smaller surgical procedures may be performed after infiltration of the operative site with the desired local anesthetic drug. Procaine (1 per cent) is the most widely used agent for this purpose.

NERVE AND FIELD BLOCKS

Direct nerve blocking is adopted when the operative site is in an area supplied by easily accessible nerves. In some areas, as for example the upper thorax, overlapping of nerves occurs so that blocking would have to be extensive. The anesthetic procedure might be of a greater magnitude than the operation itself. Nerve blocks, thus, are more practical for operations in the extremities or about the head than for those on the thorax and trunk. A field block may be considered as intermediate between a nerve block and infiltration. The anesthetic is deposited at the point of division of a nerve into branches so that the area distal to this point is anesthetized. Infiltration along the costal margin from the xiphoid to tenth rib blocks the branches of the lower intercostals to produce an abdominal field block. Anesthesia of the lower abdominal area is obtained by extending the line of infiltration along the outer border of the rectus muscle.

Brachial plexus block is widely used for anesthesia of the arm and forearm. The trunks, divisions or cords of the plexus are infiltrated with a local anesthetic solution above the clavicle or in the axilla. In the supraclavicular approach, the nerves are blocked by depositing the solution along the first rib. Pneumothorax and trauma to the great vessels are possibilities. In the axillary route, the injection is made in the medial aspect at the midline at the level of insertion of the pectoralis major. The median nerve is also blocked at the elbow or the wrist. When block is attempted at the elbow, the landmarks are the brachial artery and the tendon of the biceps at the antecubital fossa. The radial nerve is also blocked at the elbow and wrist. When block at the elbow is attempted, an intradermal wheal is raised lateral to the biceps tendon and the needle introduced perpendicular to the skin and advanced until the lateral condyle of the humerus is encountered. The ulnar nerve is blocked at the elbow or wrist also. The landmarks for block at the elbow are the groove of the internal condyle of

the humerus and the olecranon process. By combining a block of these three nerves at the elbow, anesthesia of the forearm and hand may be obtained. At the wrist, the needle is introduced between the tendons of the palmaris longus and flexor carpi radialis muscles at the level of the ulnar styloid to block the median nerve. The ulnar nerve likewise may be blocked in the same area by introducing a needle on the radial side of the tendon of flexor carpi ulnaris muscle at the level of the ulnar styloid. The radial nerve may be anesthetized at the wrist in the anatomic snuffbox.

The digital nerves are blocked on the lateral and medial aspects of the digits at the proximal phalanges. Gangrene may result from ischemia due to the injection of large volumes of solution. Brachial plexus block or blocks at the elbow or wrist are preferred.

The intercostal nerves are blocked as they course the intercostal spaces at a point in the midaxillary line on the inferior border of the rib. The femoral nerve is blocked below Poupart's ligament lateral to the femoral artery. Used alone, femoral nerve block is satisfactory for operations on the anteromedial aspect of the leg. Combined with sciatic nerve block, it is satisfactory for operations below the knee. The sciatic nerve is blocked 3 cm. inferior to the midpoint of a line drawn between the iliotrochanteric crest and the posterosuperior iliac spine. The anterior and posterior tibial nerves are blocked at the ankle for operations on the foot. The spinal nerves are blocked as they emerge from the intravertebral foramina along the bodies of the vertebrae by the technique known as paravertebral block. In the cervical area, block of the spinal nerves is referred to as cervical plexus block, in the thoracic area, as thoracic paravertebral block and in the lumbar area, as lumbar paravertebral block. Transsacral block, also a paravertebral block, is performed by passing needles into the sacral foramina through the dorsal aspect of the sacrum.

REFRIGERATION ANESTHESIA

At a temperature of 4° C. nerve conduction is retarded. An extremity which is de-vitalized and requires removal may be packed in ice for several hours and quickly amputated while still cold. The anesthesia rarely lasts more than thirty minutes. A tourniquet may be applied and the limb packed with ice for many hours until conditions for operation are more favorable in

thetia, one must remember that patients, at a later date, may ascribe symptoms of the disease to the spinal anesthetic and create a medicolegal problem. Spinal anesthesia should not be used when diseases of the respiratory system accompanied by severe pulmonary insufficiency are present. Inter-costal paralysis accompanies high spinal anesthesia, decreases tidal exchange and causes a reduction in vital capacity. Anemia is a contraindication to spinal anesthesia because the oxygen-carrying power of the blood is reduced and tissue anoxia may occur. Diseases characterized by increased intra-abdominal pressure due to distention from gas, ascites or large tumors are contraindications to spinal anesthesia because a severe irreversible fall in blood pressure may follow induction of the block in these subjects. Septicemia also is a contraindication because the organisms may be carried into the spinal canal by the needle. Spinal anesthesia should not be used for operations above the diaphragm. Infections about the vertebral column at the site of lumbar puncture are contraindications for the same reason. Psychically disturbed subjects are not good candidates for spinal anesthesia. Patients of advanced age usually develop circulatory disturbances more frequently than younger subjects because the vasomotor compensatory mechanisms are not as effective. Children are not good subjects for spinal anesthesia because they are psychically unsuited. Distortions and bony changes in the vertebral column often preclude the use of spinal anesthesia because lumbar puncture is difficult to perform.

Neurologic complications may follow spinal anesthesia postoperatively. The most vexing and annoying of these is postlumbar puncture headache, which is believed to be due to the leakage of spinal fluid from the perforation made by the needle in the dura. It is transient and leaves no sequelae, fortunately. Of more serious consequence are the neurologic symptoms which appear after spinal anesthesia. The least common and most serious of these is paraplegia, the exact cause of which is not known. Myelitis and arachnoiditis have been found in subsequent examinations after this syndrome has appeared. Pre-existing neurologic diseases and errors in technique are believed to play a role. Palsies of the cranial nerves, particularly the sixth, also appear after spinal anesthesia on rare occasions. These are related to the loss of cerebrospinal fluid and are associated with headache. Infection from

contamination results in meningitis, arachnoiditis or abscess. Backache follows lumbar puncture at times. This may be due to trauma to the periosteum, the ligaments, the intervertebral disk or to the aggravation of pre-existing skeletal muscular disorders.

EPIDURAL ANESTHESIA

In epidural, or peridural, anesthesia the spinal nerves are blocked as they pass through the epidural space. A needle is introduced at the lumbar area in the same manner as it is for lumbar puncture as far as the dura. Neither the dura nor the arachnoid is pierced. A modified form of epidural anesthesia is obtained by introducing a needle through the sacrococcygeal membrane into the caudal canal and injecting a large volume of a local anesthetic solution at this site. This is referred to as caudal or sacral anesthesia.

Epidural block is more difficult, hazardous and cumbersome to induce than caudal block or spinal block, because the needle may inadvertently be introduced into the subarachnoid space and a lethal amount of solution deposited there. The spinal nerves acquire a sheath as they pass through the epidural space. More concentrated and larger volumes of solution are necessary for penetration than are used for spinal anesthesia. Epidural anesthesia is used for the same purposes as spinal anesthesia. The indications for lumbar peridural block are few. The caudal technique, which is safer and is more easily performed, is used for rectal and other perineal operations. The possibility of headache, meningitis, encephalitis or other neurologic complications is less compared to spinal anesthesia. The drug migrates from the epidural space through the intervertebral foramen along the spinal nerves. Some evidence exists that it diffuses into the subarachnoid space. The drug does not contact the naked nerve roots or the cord, as in spinal anesthesia.

The disadvantages of peridural block are that the needle may be placed in the subarachnoid space instead of the epidural and an overdose of local anesthetic drug deposited there. Muscle relaxation is not always adequate. The level of analgesia is unpredictable and difficult to control. Drug reactions may occur because large amounts are needed for effective blocking. The drug does not always easily penetrate each of the spinal nerves and anesthesia is incomplete or segmental. The possibility of intravascular

deaths. Aspiration of vomitus and other material accounts for many cases of obstruction. The patient with a full stomach is a poor risk from an anesthetic standpoint. Irrespective of the type of anesthesia administered, whether it be local, intravenous, inhalation or spinal, the patient who has recently partaken of food or drink vomits during or after operation. Solid particles from the stomach are drawn into the trachea and bronchi and cause obstruction. The supine position, irrespective of the activity of the cough reflex, favors aspiration if vomiting occurs. Operations should be postponed if the patient has recently partaken of food or drink. Gastric lavage and emetics are of little value in completely emptying the stomach. Excess secretion of mucus results when premedication with an anticholinergic drug is inadequate. Obstruction may occur if the anesthetist is unable to maintain a proper airway because the patient is in the lateral or prone position or because the tissues in the supralaryngeal passages are relaxed or excessive. Endotracheal anesthesia obviates these difficulties. Intolerance to nonvolatile drugs such as barbiturates causes some fatalities. The use of a combination of a nonvolatile drug, a relaxing agent and an inhalation anesthetic multiplies the hazard of each drug.

Most fatalities occur during induction or at the conclusion of anesthesia, less frequently during maintenance. Nonchalance on the part of the anesthetist and carelessness or thoughtlessness may be underlying factors. In patients whose airways become easily obstructed, obstruction takes place early and the patient is asphyxiated at this time. Vomiting occurs during light anesthesia. This happens most often during induction or at the conclusion of the procedure. Irrespective of the drug and method of administration, as long as there is loss of consciousness, danger from asphyxia exists.

Deaths from spinal anesthesia are caused by respiratory paralysis or circulatory failure. Respiratory paralysis results if the drug is forced or diffuses into the upper thoracic and cervical portion of the spinal canal and causes paralysis of the intercostal muscles in the diaphragm. If immediately recognized and artificial respiration is commenced promptly, the complication is not serious. Peripheral circulatory collapse during spinal anesthesia is due to failure of neurogenic control of the vascular system. It is readily overcome by vasopressor drugs (ephedrine, desoxyephedrine or Neo-Synephrine). When

it occurs suddenly, as it does in poor-risk subjects, and cannot be promptly corrected, or if it is disregarded, cardiac arrest results. Pre-existing cardiovascular disease increases the hazard of spinal anesthesia.

PREPARATION OF PATIENT FOR ANESTHESIA

The proper preparation of the patient for anesthesia is important. The patient is hospitalized, at the latest, the evening prior to operation. Preoperative examination consists of taking a history and performing a general physical examination with special attention to the cardiovascular and respiratory systems. A urine examination rules out or confirms the presence of diabetes or renal disease. Hemoglobin determinations are important because the oxygen-carrying power of the blood is of especial interest to the anesthetist. Patients with anemia do not tolerate even mild disturbances in ventilation. A barbiturate of the short acting type or other hypnotic drug is administered at bedtime to assure adequate rest and allay apprehension. Food is withheld after the evening meal. Proper preoperative medication is important to allay apprehension and to obtain psychic sedation. A patient who is extremely apprehensive is difficult to anesthetize with an inhalation anesthetic. When nitrous oxide is used, the task is almost impossible.

Premedication is also necessary to obtain an additive effect in order to fortify a drug of low potency. Anticholinergic drugs are necessary to minimize secretions. Premedication may also be administered prophylactically to overcome undesirable side effects caused by anesthetic drugs, such as vagal stimulation, hypotension and cardiac arrhythmias.

The narcotics are the most suitable drugs for psychic sedation. They are superior to the barbiturates. Morphine is still the most suitable of the narcotics. Dilaudid, methadone, or meperidine is used for patients who cannot tolerate opium derivatives. Methadone and meperidine are satisfactory as analgesics but possess less hypnotic activity than does morphine and are, therefore, not as effective.

There has been an increasing tendency to combine ataractics with narcotics and barbiturates to enhance the sedative and amnesic effects. The most effective drugs for this purpose are the phenothiazine derivatives, such as chlorpromazine (Thorazine), and promazine (Sparine). These drugs are far from innocuous, however, because they cause a ganglionic blockade and have a

serious cases. This is tantamount to a physiologic amputation.

INTENTIONAL HYPOTENSION DURING OPERATION

A sympathectomized subject withstands blood pressures at shock levels induced by hemorrhage for longer periods than does one whose vasomotor control is intact. This principle is applied to minimize blood loss by reducing oozing in surgical procedures in which hemorrhage is anticipated. The denervation is accomplished either by using (1) a high spinal block, (2) a ganglionic blocking drug, (3) a sympatholytic drug or by (4) performing arteriotomy. When arteriotomy is performed, the blood is collected in a sterile receptacle containing an anticoagulant and retransfused. The vasomotor control remains and the advantages of sympathectomy are not obtained. The practical methods employ ganglionic blocking drugs such as hexamethonium or Arfonad. Thrombosis of the cerebral, coronary, mesenteric and other vessels may occur. Cerebral damage from local tissue anoxia, anuria and reactionary hemorrhage are other sequelae and complications. The method is reserved for exceptional situations and is one which is not used routinely.

INTENTIONAL HYPOTHERMIA DURING OPERATION

Cooling the tissues reduces metabolic activity of cells. When a central nervous system depressant is administered, the heat-regulating center is depressed and the body temperature tends to approach that of the external environment. Certain operations, such as cardiac operations designed to relieve cyanosis due to congenital defects, or vascular operations in which the circulation to an organ is interrupted for a period, are facilitated and made possible by the reduction in metabolic activity of the cells. The period of ischemia can be increased without causing undue harm. The patient is anesthetized with a volatile or nonvolatile drug and immersed in ice water or wrapped in special blankets through which ice water circulates. The body temperature is reduced to a temperature between 28 and 24° C. The procedure is not without hazard. Ventricular fibrillation readily occurs at low temperatures.

OPERATING ROOM DEATHS

Most fatalities in the operating room in which anesthesia is the primary cause are

due to. (1) asphyxia or inadequate ventilation, (2) overdosage of the anesthetic drug, (3) a combination of overdosage and asphyxia, (4) untoward reactions to drugs or (5) sudden, severe, neurogenic shock.

Often fatalities ascribed to anesthesia are found after careful postmortem examination to be due to causes not related to anesthesia. Emboli caused by clots, air or fat head the list. Sudden cardiac failure due to coronary artery disease or other cardiac ailments is the most common cause. Severe untreated or irreversible shock causes death during operation, but rarely is death sudden and unexpected. Cerebral vascular accidents are uncommon, but do occur. Anoxia, carbon dioxide excess, excitement due to inadequate preparation and the use of vasopressor drugs may precipitate cerebral hemorrhage. Death, however, occurs after operation and seldom is it sudden. Uncontrollable massive hemorrhage from technical errors may account for some operating room fatalities. Adrenal insufficiency is a rare but possible cause of sudden death during operation.

In the absence of postmortem examinations, operating room fatalities are often ascribed to obscure, highly speculative causes. The mythical status *lymphaticus* has in the past provided an explanation for technical anesthetic errors. This syndrome is no longer accepted as a clinical entity. Vagovagal reflex is another overemphasized and convenient alibi for technical errors of anesthesia. Controversy exists concerning this reflex. Its occurrence, however, is not denied, but how frequently it causes death is debatable. Available evidence indicates that vagovagal reflexes do not cause death except when complicated by anoxia. When oxygenation is adequate and no disturbance of acid-base balance exists, sudden death does not occur irrespective of the intensity of the vagal stimulation.

Fatalities due to asphyxia during general anesthesia result from: (1) reduction of the oxygen tension of the inhaled mixture, (2) obstruction to respiration from relaxed tissues, secretions, blood or vomitus or (3) inadequate tidal exchange from hypoventilation. Death is usually due to anoxia. Hypoventilation often results in respiratory acidosis which may be the causative factor rather than the suboxygenation. Deaths due to overdosage are actually asphyxial deaths because, under these circumstances, paralysis in the respiratory centers causes apnea.

Obstruction of the respiratory passages accounts for the majority of asphyxial

the stomach contents to gravitate into the nasopharynx.

4. Flammable anesthetics are not used in situations in which a fire hazard exists. Explosions may cause death of the patient by rupture of the trachea and alveoli and by other manifestations of a blast injury. Operating room personnel are not immune from injury.

5. Premedication should always be given if possible. Attempts to anesthetize patients without adequate premedication lead to unsatisfactory results.

6. The anesthetic should be administered by one trained in the principles of anesthesia. The tendency to consider anesthesia lightly is all too prevalent. A procedure of minor consequence from a surgical viewpoint may become a major one when performed under general anesthesia. The practice of relegating the administration of anesthetics to interns and other personnel not familiar with the fundamentals of anesthesia should be condemned. General anesthesia should not be administered by persons not familiar with the basic principles of anesthesia and resuscitation. Generally, physicians instructed in this aspect of medicine administer anesthetics. However, the demand for personnel to administer anesthetics is so great that nurses are also taught the basic principles and administer anesthetics under supervision and direction of the surgeon or an anesthesiologist.

7. General anesthetics are not administered in situations in which no provision is made for recovery from its effects. A recovery room with a bed, suction, emesis basins and all the necessary resuscitative paraphernalia is highly desirable.

RESUSCITATION

Resuscitation is the restoration to life of the apparent dead. In no aspect of medicine do situations requiring resuscitation arise as frequently as they do in anesthesia. There are two phases to resuscitation: ventilatory, which consists in starting artificial respiration for apnea, and cardiac, which is an attempt to reactivate a heart which has ceased to beat.

Ventilatory Resuscitation. Whenever ventilatory efforts cease, irrespective of the cause, artificial respiration is indicated. The most practical and effective method of artificial respiration in operating rooms is the intermittent insufflation technique. The mask of the inhaler of the anesthesia apparatus is held firmly on the patient's face and the rubber breathing bag is compressed rhythmically sixteen to twenty times per minute. Inspiration is active, expiration is passive, owing to the elastic recoil of the lungs. The iron lung and other mechanical respirators are used only for protracted periods of artificial respiration. When an anesthesia apparatus is not available, manual methods may be used. The most practical for the operating room is Sylvester's method because it is performed with the patient in the supine position (Fig. 6). The patient's wrists are grasped by the operator standing at the head of the operating table. The thorax is compressed with the patient's elbows. The arms are then extended over the patient's head to inflate the thorax. The procedure is repeated fifteen to twenty times per minute. The arm-lift back-pressure method of Neilsen may be used for the prone position. Mouth-to-mouth breathing is an often forgotten effective method. The

uscitation

sympatholytic effect. Hypotension difficult to reverse, which leads to serious consequences, may develop during anesthesia and operation.

The time and route of administration are important. The optimum effects are attained when the narcotic is administered subcutaneously one to one and one-half hours prior to the anticipated time of the induction of anesthesia. In urgent situations, the optimum effects are obtained within five minutes if the drug is administered intravenously at a slow rate. The narcotics are combined with belladonna alkaloids—atropine, hyoscyamine or scopolamine—which are anticholinergic substances. They are used to minimize the secretion of mucus and saliva. Scopolamine and hyoscyamine are more effective than atropine. Scopolamine depresses the cerebral cortex and enhances the effects of morphine. The sedation is accompanied by amnesia and an air of indifference which facilitates operation and obviates psychic trauma. Atropine and hyoscyamine stimulate the cortex and antagonize the sedative action of morphine. The belladonna alkaloids are administered simultaneously, even by the intravenous route. The average adult dose is $\frac{1}{4}$ grain (15 mg.) morphine with $\frac{1}{100}$ grain (0.6 mg.) of belladonna alkaloid. For patients beyond the fourth decade of life the morphine is reduced to $\frac{1}{6}$ grain (10 mg.). Patients in the sixth and seventh decades tolerate less— $\frac{1}{8}$ to $\frac{1}{6}$ grain (7.5 to 10 mg.). Those who are older require still less— $\frac{1}{12}$ to $\frac{1}{8}$ grain (5 to 7.5 mg.). The belladonna alkaloid is reduced correspondingly in a ratio of 1 part to 25 parts of morphine. Morphine is omitted if basal narcosis with an intravenous or a rectally administered drug is contemplated. In infants and children, ultra-short acting barbiturates may be administered rectally for basal narcosis (1 gm. for each 50 lbs. of body weight) one-half hour prior to induction of anesthesia. Preanesthetic sedation is desirable but is usually omitted if the patient is to be ambulatory immediately after operation. Ambulation after the administration of narcotics and hypnotics or general anesthesia is undesirable. Ataxia, drowsiness, nausea and vomiting are common in ambulatory patients after narcotics are administered. If the patient is hospitalized, as he should be for most surgical procedures, morphine and scopolamine in the usual doses are employed. Barbiturates are recommended prior to regional anesthesia to

allay apprehension and to minimize or avoid convulsions due to local anesthetic drugs. Barbiturates completely antagonize or prevent stimulation by an overdose of a local anesthetic drug in basal narcotic doses only. Secobarbital or pentobarbital ($1\frac{1}{2}$ grains, 100 mg.) orally or intramuscularly one and one-half hours prior to operation allays but does not prevent excitement and convulsions. All efforts should be made to perform the operation under circumstances which permit the use of premedication. Many a successful regional anesthetic procedure has been classed as unsatisfactory because the patient was apprehensive.

PRECAUTIONS

There are certain generalizations which are applicable to all forms of anesthesia but more particularly to general anesthesia.

1. No general anesthetic, no matter how brief in duration is the anesthesia or how light the plane, should be administered in situations in which there are no provisions for immediately instituting artificial respiration. The apparatus employed for inhalation anesthesia is used to administer artificial respiration by the intermittent insufflation technique. This method is wholly adequate for resuscitation under circumstances encountered during surgical anesthesia. Unless an unimpeded airway is established, no method of artificial respiration is successful. Airways of the pharyngeal type are satisfactory for relieving supralaryngeal obstruction. Contrary to certain teachings, endotracheal intubation is not always necessary for resuscitation. Valuable time is often wasted in attempting to introduce an endotracheal catheter before artificial respiration is instituted. Intubation is indicated only when the usual measures for establishing an airway fail.

2. A suction apparatus for the exclusive use of the anesthetist should be in each operating room. A curved metal suction tip which permits cleansing secretions from the hypopharynx is essential. A catheter is unsatisfactory for this purpose because the patient emerging from anesthesia clamps his jaws and bites down upon it. Besides, catheters are limp and are difficult to direct into the pharynx in order to accomplish thorough cleansing.

3. The operation should always be performed on a table which can be tilted to the head-down position; in the event vomiting occurs aspiration is prevented by allowing

operator inflates the lungs by placing his lips to those of the patient and pinching the nose. Too often resuscitative efforts fail because they are not instituted soon enough and because the airway is poor. Respiratory stimulants are rarely of any value for resuscitation.

Cardiac Resuscitation. The term "cardiac arrest" is used to designate unexpected cessation of effective cardiac activity occurring in the operating room or immediately after operation. The causes of cardiac arrest have been enumerated in the discussion of operating room fatalities. When cardiac arrest is suspected, the chest should be opened immediately and attempts made to resuscitate the heart. Cardiac arrest is due to asystole or ventricular fibrillation. It is imperative that massage be instituted as quickly as possible so that an effective head of blood pressure is maintained in the vascular system. Artificial respiration must be carried on simultaneously to provide proper oxygenation. Unless resuscitation is instituted immediately, cerebral damage invariably results if the patient survives. It is useless to open the thorax and massage the heart unless effective artificial respiration is performed simultaneously.

The technique of cardiac resuscitation is simple. An incision is made between the fifth and sixth ribs on the left side from a point one inch lateral to the sternum to avoid the internal mammary vessels. The heart is grasped between both hands and compressed rhythmically at a rate as near normal as is possible so that an effective arterial pressure is maintained. If the myocardium is atonic and depressed, 0.25 mg. epinephrine (1:1000) or 5 cc. of 5 per cent calcium chloride is injected into the right atrium. Physical methods are necessary to reverse ventricular fibrillation; drugs are ineffective. The heart is shocked with the ordinary 110 volt-60 cycle alternating current. The shocks, $1\frac{1}{2}$ amperes for one-tenth second, are delivered by broad electrodes placed over the surface of the heart. Asystole develops after several shocks and massage is maintained until the beat resumes. Defibrillators specifically designed for the purpose are now available which should be a part of emergency operating room equipment.

factors which affect a burned patient. It is no longer just a local wound to be treated; it is a wound affecting the general condition of the patient. The wound and the systemic disturbance must be treated at the same time. Better understanding of the treatment of shock and altered nutrition, the control of infection and early coverage by skin grafting of the burned wound have been of great value in the improved management of these patients.

Burn wounds are caused by the contact of the skin with sufficient thermal energy to create pathologic changes within the skin and then, secondarily, a response by the patient. These wounds may be caused by contact with flame, scalding water, steam, electricity and chemicals and the irritation of poison gases. Accidents from gasoline and kerosene explosions are a common cause of deep burns. One type of burn is commonly referred to as the "flash burn," and this is not actually a special type. Such a burn is caused by exposure to any high intensity heat for a very short interval and is confined to the exposed skin, such as on the hands and face. It may easily occur in a gas explosion.

Burns are most common in individuals in the extremes of age and mortality rates are likewise higher in these groups. Males are more often burned than females, but the mortality is higher in the female. Burns have been a notorious cause of permanent deformity and loss of earning power and constitute a potent source of hospital bed occupancy following trauma. A study made of bed occupancy has shown that about one-third of burned patients require hospital care. The number of hospital days spent is unknown, but it has been estimated to approximate several hundred days in a hospital for each subject who has died as a result of burns. In 1956, there were 6405 deaths from fire and explosions in the United States. It is further estimated that the yearly incidence of seriously burned patients is roughly twenty times greater than the number of thermal deaths. Much can be done prophylactically by educating the public concerning the dangers both in the home and in the factory of the careless use of kerosene, gasoline or other flammable liquids or articles. Most of all the burning injuries of children could be avoided if education were practiced. Outlawing the sale of flammable clothing has been shown to be important in reducing the incidence of serious burns. Such clothing, however, is still

sold. In time of war the incidence of burns in combat zones and in the rear areas from gasoline explosion, flame throwers, incendiary bombs or simple accidents creates large numbers of long-term casualties. Atomic bombings can, of course, be a source of a large number of seriously burned casualties.

Burned patients constitute a high percentage of those seen following catastrophes and it is necessary that hospital personnel be aware of the importance of being prepared for a sudden influx of large numbers of burned and injured patients. This would mean previous planning for their care and a stockpiling of the few essential items necessary for local wound care and the treatment of shock.

Depth of Burning Injuries. The usual classification of burns is based on the depth of the injury: first, second and third degree burns.

First degree burns are superficial injuries involving the epidermis and heal rapidly without scarring.

Second degree burns are also called *partial thickness burns*; they heal by epithelial regeneration if infection and other irritations can be avoided. The skin destruction involves varying depths of the corium as well as the epidermis. Two types of second degree burns are recognized: superficial partial thickness and deep dermal burns. A superficial partial thickness burn heals within ten to fifteen days. When recently healed, the surface lacks normal pigmentation. The color and architecture of the healed skin eventually approach normal skin after a few months. Deeper burning within the skin may leave sufficient viable epithelial appendages which permit slower but eventual epithelization of the surface. The deeper second degree burns, called deep dermal burns, may heal within four weeks. The healed surface consists of thin, fragile skin called scar tissue epithelium. Future replacement of this skin with a thicker skin graft is frequently necessary to improve both function and appearance.

In *full thickness*, or *third degree*, burns the entire thickness of the skin is destroyed beyond repair and frequently the injury involves the underlying tissues. The depth of this injury may extend to, and include, the muscles, nerves and tendons. In electrical injuries, involvement of the bone and joints is not uncommon. These deep burns cause death of all tissues which have received sufficient thermal energy. Eventually

THERMAL AND IRRADIATION INJURIES

Burns

By JOHN L. BELL, M.D.

Burns are thermal wounds which vary greatly in extent, depth and location. The responsibility of the doctor to the burned victim begins with the management of the acute injury. It should not end until the patient has been restored to an acceptable position in society. Any physician may be called upon and should be able to render adequate emergency care to burned patients, especially in the time of a catastrophe. In severe cases, however, the continuation of treatment often requires the attention of a surgeon who is familiar with the more intricate aspects of deep wounds resulting from thermal injury. In burns the objectives of care are to preserve life, to obtain healing of the wound as early as possible and to minimize loss of function and disfigurement.

Initially, the magnitude of the burn injury can be anticipated by assessing the size and the depth of the burn. In extensive burns, immediate systemic alterations occur and should be managed before extended care is given to the local wound. Superficial

and deep burns should be differentiated as soon as possible because the latter often require well planned surgical procedures in order to achieve early closure of the wound with a minimal loss of function. Acute burns, superficial or deep, provide highly susceptible avenues for local or invasive infections until complete healing has been attained.

Superficial burns heal spontaneously if infection and mechanical or chemical irritation of the wound are avoided. The topical application of drugs to burned surfaces has little effect upon the ability or rate for spontaneous healing of superficial burns. The skin is destroyed in deep burns and healing is obtained by skin grafting after removal of the necrotic tissue and the proper preparation of the recipient site.

With the renewed interest in the treatment of burns brought about by the recent wars and the atomic and thermonuclear bombs, the therapy of burns has shown great advancement. This progress is due to better understanding of the combination of

be accurately assessed immediately upon inspection following the injury. A fairly accurate estimation can be made with the help of the Berkow scale for estimating the extent of a burn (Fig. 1). A more rapid but a cruder estimation can be made by the use of the rule of nines (Fig. 2). The employment of this method, however, frequently leads to dangerous overestimation of the percentage of body surface involved.

Clinical Course of Burning Injuries. When sufficient heat is applied to the body surface to create a burning injury, there is precipitated a chain of events which is now quite well known. When the extent of the burn is sufficient—beyond 15 to 20 per cent of the body surface—there is a general systemic response known as burn shock. Immediately after the injury, there is a period of shock, during which the patient is often comatose. The patient is protected from the cooler air.

In first degree burns skin redness is not persistently painful. This type of injury usually evokes little general response. Partial thickness burns are common after a scalding injury and, if these are sufficiently large, burn shock may occur. The wounds heal slowly and the healing rate depends upon the avoidance of infection and other irritants which could easily convert a superficial, incomplete thickness burn into a deep or whole thickness variety. When not infected or irritated, these burns usually heal. Healing occurs by the ingrowth of epithelium from the remaining elements, such as the sweat glands and hair follicles.

The third degree, or whole thickness, burns occur most commonly when clothing catches fire and if the area is large enough—beyond 15 to 20 per cent of the body surface—will produce a shock state. The local burned wound appears charred frequently but may be white or range from brown to black in appearance. It is anesthetic to sensory stimuli. The full thickness burn is usually surrounded by a pink areola of less deeply burned regions which will epithelize and heal within ten to twelve days, leaving an open wound of varying size which is covered eventually with granulation tissue. The local wound can easily become infected after the first few days because of the presence of dead tissue at body temperature, which encourages any type of infection. The eschar will begin to separate from the unburned tissue about the fifth to eighth day and if neglected will ultimately slowly slough away. This slough acts as a seques-

trum and the host attempts to separate it from the underlying structure. The autolysis of the burned tissue accounts for a marked increase in wound discharge. Later, if the wound is disregarded, local or invasive infection supervenes.

A burning injury will evoke a marked endocrine or stress reaction, which is almost maximal in degree. Initially, the patient has great fear of pain and scarring and later if the burn becomes chronic the patient will lose morale and exhibit definite psychic changes. Extensive burns commonly produce this change and patients refuse to eat and complain bitterly of even minor discomforts. Weight loss and profound secondary anemia can become very marked as a result of the constant loss of protein from the wound. If infection has been added, the burn is thus deepened and protein and fluid loss is accentuated.

Burn wounds should be considered as potentially contaminated, open, soft tissue injuries, and as such demand careful local care at all stages to control infection until healing has occurred. It is the objective in all burn wounds to convert the open contaminated wound into a closed wound as early as is possible and practical. Any unnecessary delay in converting these open wounds into closed wounds deepens the injury and, when a sufficient extent of the body surface is involved, life itself may be jeopardized by septicemia.

Pathologic Changes of Burned Surfaces. The first degree burn is an injury of a superficial nature in which blebs do not form. In this type there is early redness and some edema but no necrosis.

The second degree, or partial thickness, burn denotes an injury in which there is superficial necrosis and, initially, there is edema and bleb formation. The blebs are found within the layers of the skin and may be sufficiently large to rupture spontaneously. The burned surface is either pink or red and mottling can usually be noted. Exudation may be profuse. The wound extends into the dermis and there are viable remnants of epithelium, such as sweat glands and hair follicles, from which healing will occur without the necessity of grafting. The deep dermal burns are those in which there are only scattered skin appendages left for regeneration. It is impossible to diagnose a deep dermal burn in the acute phases. A healed burn of this type has a thin, fragile epithelial covering, which breaks down frequently after minute trauma.

Below are given head, thigh and leg percentages for children from 1 to 5 years of age

such a wound demarcates and the body attempts to slough off the damaged area as a foreign body, creating a large open wound which must be closed by skin grafting.

Most burns are irregular in depth because of the protection of clothing or the anatomic variations in the thickness of the skin. The usual pattern is that of the greatest depth being in the center of the injured area and lessening of depth toward the periphery of

the wound. The depth of the burn at the time of initial inspection immediately after the injury is difficult to assess, except in those in which there is actual charring of the skin with anesthesia of the area, which indicates complete death, or a whole thickness burn.

Extent of Burns. The size of the burned wound is another indication of the severity of the injury. There is a definite rough correlation between the extent of the burn and the degree and severity of burn shock. However, there is a wide variation in the individual response to the injury and often the extent of the burn can be misleading, for in one patient a 15 to 20 per cent body surface burn can be overwhelming, while in another patient, similar in size, it seems to evoke a minimal response.

A common error is that of overestimating the extent or the percentage of the body surface burned. The reason for this is that the exact extent of the burn wound cannot

Figure 2. A simplified method of estimating body surface burned—"the rule of nines." This is a crude method and the surgeon must be constantly aware that he must not overestimate the body surface burned

that there is a diminished response as measured by the steroid excretion and the eosinophil count.

The hematologic changes which occur after a burn are of two varieties. First, the red cells are often trapped and held within vessels which are permanently damaged by the heat. Moreover, the red cells are very susceptible to heat and this increases their fragility. This marked fragility produces a great increase of cell debris which can produce hemoglobinemia, which, when sufficiently severe, can affect the function of the liver and the kidney. The continuation of hemoglobinemia can produce delayed jaundice and hepatitis. When these occur, the prognosis is greatly altered.

The second response of the blood is hemocoagulation, due to sudden and continued withdrawal of the fluid portion of the blood into the burned region. The blood is more viscid than normal and a rising hematocrit reading is common in the immediate postinjury course. With the increase in the viscosity of the blood, the blood volume is actually lowered and the body attempts to restore and maintain the blood volume by withdrawing from the available fluid reserves, thus creating dehydration of the unburned regions. In profound shock, constriction of the peripheral blood vessels is common. Occasionally these markedly constricted vessels are filled with black syrup-like blood.

There is an immediate leukocytosis which is both true and relative, owing to the concentration of the blood. This leukocytic response subsides unless infection supervenes. The blood changes are only a matter of degree and will not be apparent in a patient who does not exhibit some form of burn shock.

Changes in the urine depend upon the maintenance of the blood supply to the kidney. If this blood supply is reduced as the result of burn shock, the volume of urine is reduced and the specific gravity increases. Albuminuria is common. Later, nitrogen excretion is greatly increased, which correlates well with the stress response of these patients. In patients with serious burns in whom there is a marked breakdown of red cells, hemoglobinuria may occur. Urinary changes will continue until there is correction and improvement of the circulating volume of blood. After three to four days, diuresis will be noted and this is the result of the edema fluid being reabsorbed.

The blood chemical changes following a

burn are due in part to the dehydration of the blood and, secondly, to the alarm reaction. The sodium is conserved following a thermal injury and the blood level is lowered. Potassium may be lost, particularly when there is diarrhea or vomiting. Transient hyperglycemia occurs after the burn. There is a temporary rise in plasma proteins and later, with continued withdrawal of the fluid portions which are high in proteins, there is produced a hypoproteinemia. The circulating proteins are drawn into the burned tissues and this state remains until there is a reversal of the edema fluid from the burned regions, usually in three to four days. A dilution of the circulating proteins occurs after the diuresis. The protein loss may continue and be accentuated if infection has been added. Reversal of the albumin-globulin ratio occurs and such severe lowering of the proteins may produce a hypoproteinemic edema.

The studies on vitamins have shown a marked reduction in the ascorbic acid levels immediately following a burn. This becomes more marked if the burn has been allowed to become chronic.

The pathologic changes seen following a burn depend upon the extent and the depth of the burn, and particularly upon the patient's individual response to the injury. Not all burned patients will exhibit all of the changes mentioned, not even those with extensive burns. The injuries do not follow an exact pattern. In some patients the injury is an overwhelming assault and causes marked tissue damage and chemical changes, protein loss may be rapid and marked weight loss may occur. The body fat is consumed first and then the protein mass is used to provide sufficient calories to maintain the increase in the metabolic rate of such patients. There is a catabolic response in each patient which creates a negative nitrogen balance. This can be limited when there is proper protein replacement by blood, diet and supplementary feedings. When protein loss is allowed to continue, the nitrogen reserves of the body can be so depleted that healing can never be accomplished and it is in these patients that infection is common and all attempts at skin grafting fail.

Infection added to the large open wounds creates havoc and septicemia is a common cause of death. Pyogenic infections are greatly enhanced because of the presence of dead tissue, body moisture and body heat. When malnutrition and secondary anemia

The pathologic changes which occur within the skin and subcutaneous tissue, or the deeper structures, depend naturally upon the intensity of the heat and the length of time that it has been applied. Full thickness burns may immediately show heat coagulation and necrosis. The underlying subcutaneous tissues may be dry and hard and surrounded by marked edema. Subcutaneous vessels are filled with thrombi. When involvement of the muscle has occurred, the tissue immediately becomes very pale and friable. In electrical burns, the bone may be involved but the demarcation of the dead bone is very slow and takes many weeks.

Systemic Alterations Following Burns. The burning injury evokes a response which is characterized by rapid pouring out of fluid into and around the wound. It is as though a fluid barrier were thrown about the site to wall off the injury. This fluid comes from the local vessels, lymphatics and capillaries and also from the fluid within the cells which have burst as the result of the heat applied.

The fluid which escapes into the burned area is carried away by lymphatic drainage from the local site, but soon the amount of fluid exceeds the ability of the lymph channels to withdraw it and the accumulation will pile up in the interstitial spaces, thus producing edema, not only of the wound but also of the area surrounding the wound. Large amounts of fluid can be hidden when infiltrated deep into the soft tissues and about the burned organs. This can be misleading if one does not realize that this amount of fluid can represent a high percentage of the total circulating fluid volume of the body. The fluid escaping from the circulation into the wound is not identical, but is similar, to plasma. It has a lower concentration of protein than has plasma but has the same concentration of electrolytes. In some instances, the swelling and the edema may become so intense as to jeopardize the vascular supply of the part.

The pathologic changes in organs which are not directly involved by heat could be assumed to result from reduction of the circulating blood volume, first creating immediate dehydration of these organs and later, if the blood flow continues to be lowered, depriving these organs of their blood and oxygen, and hence interfering with their function. This is apparent in the kidneys, brain and liver, where irreversible changes may occur.

The gastrointestinal tract is not often directly affected by heat, but there may be an indirect response varying from anorexia to vomiting and paralytic ileus is a common complication in patients with severe shock. One of the rare complications of the severe burn is a Curling's ulcer, an ulceration of the upper gastrointestinal tract, and in some cases the only indication is hematemesis or blood in the stools. In others there may be an actual perforation of the ulcer, causing peritonitis and death. The cause of Curling's ulcer is as yet unknown. It has been ascribed to the general stress response in which gastroduodenal perforation is not uncommon.

Pathologic changes within the respiratory tract depend upon the actual inspiration of either hot fumes or poison gases, seldom does flame itself penetrate beyond the upper respiratory region. The upper tract response is edema, which may be so marked as to produce swelling of the arytenoid tissues which will actually obliterate and obstruct the larynx. Lower respiratory tract injury produces damage to the bronchial and bronchiolar epithelium. Spasm and edema and, eventually, desquamation may cause respiratory obstruction and death. In lower tract injury flu

altered changes other than the usual responses which would be elicited in shock from any cause. There is, however, a great tendency for thrombophlebitis to occur because of the prolonged period of thickening of the blood, due to hemoconcentration. Thrombotic phenomena are not rare.

With reduction in the circulating blood volume, there is a reduced cardiac output in burn shock and, late in the course, the blood pressure will fall, but this has no neurogenic or endocrine etiologic significance. It is purely due to lack of sufficient blood volume to maintain the blood pressure at a working level.

Burning injuries evoke a general endocrine response. The alarm reaction in burns is maximal. Initially there is a rapid rise of the ketosteroid excretion and a lowering of the number of eosinophils. There is a loss of nitrogen through the kidneys, which accounts for the negative nitrogen balance which appears in a burn patient after burn shock. This response to stress will continue until the wound is healed, while complications, such as infection, may prolong the response. In fatal cases it may be seen early

suggested are only a guide to start the therapy.

It is apparent that no formula takes into account the variation in the individual's response to the different types, depths and extent of burns. No formula takes into account the age of the patient, the previous health or hydration or the individual's reaction to trauma. Clinically, it is seen that children with extensive scalding have shown accentuated shock response for there is a very intense persistent fluid loss into and from the wound. This is more apparent than in patients with a burn of similar extent due to a flame type of injury in which the skin is hard and charred, prohibiting the oozing of fluids from the wound. However, the damage to the red cell mass associated with a flame burn is greater than that due to scalding. Anemia always occurs earlier following a flame burn. Actually, there is true anemia which is not apparent until late, when diuresis has occurred and the hemoconcentration has been alleviated.

A formula may be useful as a guide to initiating treatment of burn shock. The formula propounded by Evans, in 1952, is based upon the percentage of body surface burned times weight in kilograms. This formula permits an estimation of the amount of fluid which is to be provided in plasma, plasma expanders or blood needed during the shock state. Evans believed that an equal amount of isotonic saline solution should be administered during the shock phase and that some fluid should be given for renal excretion and the insensible loss.

For example, the fluid requirements in the first twenty-four hours for a man weighing 70 kg. and suffering from a 30 per cent burn would be as follows:

Plasma, plasma substitute or whole blood	$70 \times 30 = 2100$ cc.
Saline solution—0.9 per cent	$70 \times 30 = 2100$ cc.
Dextrose in water—5 per cent	2000 cc.
Total in the first 24 hours	6200 cc.

Evans recommended that the fluid requirements should be given in the following manner. One-half of the total estimated fluid for the first twenty-four hours should be given in the first eight hours after burning, and one-quarter in each of the subsequent eight-hour periods of the first day. During the second twenty-four hours, the colloid and electrolyte requirements are roughly one-half of the previous amount recommended for the first twenty-four hours. Evans wisely recommended that, after forty-

eight hours, fluids should be supplied mainly by the oral route. Fluid requirements for a patient with burns involving more than 50 per cent of the body surface should be estimated as 50 per cent surface burns, and never for more than this, for no patient should receive more than 10,000 cc. of fluid in the first twenty-four hours. A modification of the Evans formula is advocated by the Brooke Army Medical Center. The Brooke formula differs from the Evans formula in that an electrolyte-colloid ratio of 3:1 is proposed.

There are but few chemical or laboratory tests which will aid in judging the efficacy of burn shock therapy. However, constant observation of the general appearance of the patient, the pulse rate, the color and the degrees of restlessness and thirst will provide indications of progress. The most important and best index for judging the adequacy of burn shock therapy is the amount of hourly urinary excretion (Fig. 3).

In any patient with clinical signs of shock, or in any in whom the extent of the burn suggests the possibility of burn shock, an indwelling catheter is placed in the bladder so that the hourly urinary flow may be accurately recorded. The initial residual urine in the bladder is examined in the usual routine manner. The objective of all shock therapy is to give sufficient fluid to obtain an average urinary flow of 25 to 50 cc. per hour for the average adult.

Most burned patients can tolerate limited amounts of oral fluids if administered at a definite rate that does not result in overloading the gastrointestinal system. Although the burn shock patient is very thirsty, this condition must be combated by giving fluids intravenously, because only limited amounts of oral fluid can be tolerated without vomiting. Vomiting is to be avoided because of the additional loss of electrolytes which will only further endanger the patient. Clinically, it is found that an oral intake for an average adult of only 200 cc. per hour is adequate and that this reduces the total amount of fluids needed by vein. This amount of fluid given by mouth is well tolerated if it is a chilled solution consisting of salt and bicarbonate of soda. The solution contains 1 teaspoonful of salt and $\frac{1}{2}$ teaspoonful of bicarbonate of soda to a quart of water.

The colloid solutions are given in the form of either whole blood, virus-free plasma or one of the plasma expanders, and no rigid rule can be given as to how much of each

are allowed to progress, many strains of virulent pyogenic bacteria can readily break through the wound barrier and gain access to the circulation.

Burn Shock and Its Treatment. The systemic response to burning injuries is called *burn shock*. This usually follows a burn which is greater than 15 to 20 per cent of the body surface, but it should be anticipated in any patient with burns which involve more surface area than the "flash burn" areas, that is, the exposed hands and head.

There are many as yet unexplained reactions in burn shock and too often these are reputedly said to be due to "toxins." Burn shock is a combination of the responses of the local bodily defenses against a burning injury with resulting effect on the chemical composition of the blood plus the interplay of the endocrine glands. Burn shock results in reduction of the circulating blood volume, both as to the quality and quantity of the blood. The blood volume is reduced because of the continued withdrawal of serum and plasma-like substances into the burned area, producing local edema as if the body were attempting to isolate the injury or to wall it off with a protective fluid barrier. This continuing withdrawal of fluid portions of the circulating blood produces dehydration of the unburned portion of the body and this continuing process increases the viscosity of the blood and produces a hemoconcentration. The reduction of circulating blood volume is reflected in the amount of blood and oxygen supplied to the vital organs, such as the brain, the heart and the kidneys. Further, a thermal injury will trap and destroy a certain amount of the red cell mass. Therefore, the fluid, plasma and red cell volumes are reduced as the result of burn shock.

Burn shock is a steadily progressive, constantly changing phenomenon which continues for approximately forty-eight hours and will during this time demand constant attention. Edema formation is marked and occurs at a rapid rate during the first few hours. Clinical evidence indicates that burn shock reaches its maximum within four to twelve hours following injury.

The clinical picture of burn shock clearly manifests itself when the patient is carefully examined. In a patient who has 20 per cent or more of the body surface burned, there will be obvious signs of burn shock. The patient is moderately restless and apprehen-

sive and there will be pallor or cyanosis of the extremities and the mucous membranes. The extremities vary in temperature from cool to cold and sweat in variable degrees is observed. The patient rarely complains of pain but often will complain bitterly of the cold and ask to be covered by a blanket. Most patients are apprehensive and, if the shock is untreated, they become rather apathetic and this apathy may continue to an actual comatose state and death. The pulse rate is generally rapid and becomes more so as the shock progresses. This is far more notable, as are all other signs, in children and in elderly patients. The respiratory rate is slightly increased in burn shock and respirations are usually shallow. Thirst, a common complaint, is one of the outstanding clinical signs, for it is far more pronounced in burn shock than in shock produced by other trauma. Occasionally, the thirst is even accompanied by vomiting. The severely burned patient will exhibit a collapse of the peripheral veins and it is difficult to obtain blood samples from the usual available veins without performing a cut-down. It is good practice to perform a cut-down and insert a good-sized cannula, which will be the lifeline for later therapy. Occasionally in far advanced shock, the blood within the collapsed peripheral veins is black and syrup-like in consistency. The blood pressure is not an accurate guide as to the presence or probability of burn shock.

The restlessness associated with burn shock is due to anoxia of the brain and is too often interpreted by the doctor as being due to pain. The use of morphine, given subcutaneously, will not aid this situation, but rather its administration may obscure the usual findings of burn shock. It is imperative that attention be directed to the restoration of the blood volume to a working level. There is no drug which will aid or prevent burn shock.

The amount of fluid which must be provided to bring back the blood volume to normal, and to maintain it during the interval of burn shock for each patient, must be sufficient, first, to restore blood volume and the red cell mass to normal, second, to maintain blood volume at a normal range during the continued withdrawal of fluid, that is, the first forty to forty-eight hours, and, third, to allow for renal deviation and insensible loss. It cannot be stressed too much that the amount of fluid necessary will vary widely from patient to patient and the formulas

or plasma substitute has been given, it has been the practice to administer whole blood at the ratio of two parts of virus-free plasma, or substitute, to one of whole blood. In extensive full thickness burns, the damaged red cell mass may be partially restored by the early use of whole blood transfusions.

Whenever vomiting has occurred, additional electrolytes must be administered. If the urinary flow exceeds 50 cc. an hour, the amount of fluid given intravenously should be reduced for it is obvious that too much fluid is being administered. If the urinary output is reduced to 15 cc. or less per hour, inadequate amounts of fluid are being provided. The amount of fluid given orally is constant; the only variable factor in the treatment of burn shock is the rate of the flow of the solutions given intravenously, which should be adjusted to the patient's general condition and the rate of urinary flow. Obviously, the amount of fluid given and the amount of urinary output are altered with the extremes of age. In elderly patients, and in any patient with a pulmonary burn, it is best if the urinary output does not exceed 25 cc. per hour, for there is always danger of overloading the cardiovascular and pulmonary systems.

At times the patient will benefit by the use of an oxygen tent, but this is only empirical for the oxygen-carrying capacity of the blood in burn shock is not greatly altered, unless there has been marked pulmonary injury from noxious gases or actual heat.

After burn shock has been controlled, there is beginning resorption of edema fluid from around the wound and large amounts of electrolyte solutions given at this time may overload the cardiovascular system and cause pulmonary edema. Diuresis occurs after the forty-eighth hour and continues for another one to two days. Careful observation of the urinary output and the patient's clinical course is necessary during this time.

Nutrition. After the patient has entered the phase of diuresis, a period of negative nitrogen balance with marked excretion of nitrogen-bearing colloid is apparent. Clinically, a series of events which are very evident will be seen. Progressive secondary anemia and rapid weight loss with marked reduction in the protein level of the blood and a reversal of the albumin-globulin ratio occur. The surgeon should anticipate these events and combat them in a logical manner.

In order to combat weight loss and anemia, the patient should be provided with an adequate diet, whole blood and vitamins

so that this deterioration does not continue and that his general well-being will not be so lowered that a regrettable infection develops in which the wound is subjected to the ever-present danger of contamination.

The nutritional problem of a burned patient after recovering from burn shock and during the phase of healing can be very serious if there is any delay in complete closure of the wound. If the timetable of management of the patient can be kept so that the shock is efficiently treated and the patient is maintained at a good healing level, then the burn slough can be rapidly removed and the wound closed by the use of skin grafts within three weeks from the time of injury. After closure of the wound, nutritional problems are seldom troublesome for loss of protein from the wound ceases. When the wound is closed early, there is likewise less danger of infection. Any delay in wound closure or failure to maintain the patient's nutritional level will be manifested by the sluggish appearance of the granulating wound and the poor growth of epithelium from the wound's edges. Actually, the appearance of the burn wound is a reflection of the patient's general condition.

One should attempt to minimize the altered balance of metabolism by providing the patient with a diet which will supply the elements needed to compensate for the marked protein loss and meet the demands of tissue repair, red cell regeneration and metabolism. The dietary requirements are determined largely by the extent and depth of the burn. The diet must be palatable, yet properly balanced, and must be high in protein content.

It is recommended that there be a daily intake of from 2 to 3 gm. of protein per kg. of body weight, and from 3000 to 6000 calories per day as a basic minimum. Fat in the diet is of value because it will provide sufficient calories while sparing the ingested proteins which are so necessary for hemoglobin formation and wound healing. In the occasional patient who cannot tolerate this diet, as a supplementary measure it is wise to use intragastric tube feedings of high protein liquid mixtures to provide from 2000 to 3000 calories a day. The various high protein mixtures include some form of whole milk, powdered milk or protein concentrates. Mixtures high in fat content sometimes produce diarrhea and when this occurs adjustments must be made.

Marked vitamin deficiency, particularly of vitamin C, accompanies severe burns. Daily

wound, namely, the conversion of the open contaminated wound into a clean closed wound as rapidly as is practical for the patient. In burns, skin grafting is often demanded in closure of the wound.

First aid for a burn can be very simple in civilian practice, for all that is required is to protect the wound carefully and to transfer the patient immediately to a hospital where facilities are available for complete care. The application of home remedies, such as ointment, butter and lard, too often adds further delay and always adds unnecessary contamination. Simple protection by the use of the cleanest available material to exclude the air is the most practical type of first aid.

Immediately upon admission to the hospital, the patient should be quickly assessed as to the type and, roughly, the extent of the burn. Many minor burns do not demand hospitalization nor will the patients exhibit shock, but, when the burned area is larger than the "flash burn" regions, in all probability hospitalization will be required and burn shock may be anticipated.

The initial care of the burn is performed without the use of anesthesia. For those with extensive burns, anesthesia is contraindicated because of its deleterious effect on the accompanying burn shock.

Narcotic drugs are not routinely administered to the acutely burned patient. If pain is a factor, a small dose of morphine may be given intravenously. In patients with burn shock, the subcutaneous injection of morphine is dangerous and useless. In these patients, the drug cannot be absorbed until the circulatory deficit has been corrected. If repeated doses have been given, morphine poisoning can occur with the return of circulatory efficiency. Restlessness is a symptom of severe burn shock and is not an indication for a narcotic. Pain can be greatly diminished if the local care is undertaken in a room which is moderately warm and where draughts of air can be avoided.

Under aseptic conditions, the burned site and the area well beyond it in all directions are gently cleansed with large pledgets of sterile cotton that have been dipped in a mixture of bland soap and warm sterile water. The wound is carefully flushed and all obvious blebs and loose bits of skin are removed. The procedure can be done carefully and yet rapidly. It is remarkably painless if gentleness is practiced and sterile water at body temperature is used for washing and flushing.

A single layer only of sterile, fine-mesh

gauze is placed over the wound and the entire area is then covered with a previously prepared dressing. The fine-mesh gauze may be impregnated with a light coating of petrolatum prior to its sterilization. This is held in place by some form of bandage which produces a uniform compression dressing. The compression dressing must not be tight, and must have a definite amount of resiliency. If the burn involves an extremity, immobilization is secured by applying a splint. When the wound is covered and air is excluded, there is almost complete absence of pain.

Every hospital or first-aid station should be equipped with previously prepared sterile dressings always in readiness for burned patients or extensive open injuries. These dressings are made with 24-ply Cellucotton with fine-mesh gauze attached to one side. They are made in two sizes, one suitable for small burns or burns of the hand and forearm, the other sufficiently large for either the posterior or anterior trunk, or to encase the entire lower extremity of an adult. These stored sterile dressings can be taken out quickly and applied rapidly. They are useful not only for emergency local care of the wound but also in later care if skin grafting is required. The dressings are of sufficient thickness to allow uniform compression to the open wound.

The petrolatum-impregnated gauze is used only to permit ease of removal later; it is merely a mechanical agent and has no healing power. At the time of removal, the gauze should be gently lifted away to minimize tearing of the new epithelial layers.

The dressings are usually not disturbed for from five to eight days unless there is indication that they should be restored.

The initially applied burn dressing may be useful in most areas except the face and the perineum. These regions are usually left exposed.

One of the rediscovered methods of local care is that which is termed "exposure." This method relies on exposing the burned wound to the atmosphere and its value lies in drying of the wound which reduces the possibility of infection. It eliminates the necessity

of the patient are required. The dry crusts are allowed to remain in place until epithelization has occurred, permitting the crusts to be lifted away.

Exposure of a burned area is initially pain-

vitamin supplements should be given in the following amounts: vitamin C, 1000 to 1500 mg., thiamine, 50 mg., riboflavin, 50 mg., and nicotinamide, 500 mg.

During the phase following burn shock and until the wound has healed, whole blood transfusions are often required. It is essential to maintain the hemoglobin and the total blood protein at a high level to combat infection and to facilitate normal epithelization. As a good working basis, the total proteins should be kept above 6 gm per 100 cc., but it must be cautioned that any estimation of the circulating blood protein is no criterion of the body stores of protein, which can be greatly depleted. Clinically, it is of value to keep regular recordings of the patient's weight for this is a remarkably accurate guide to his progress. If this is not practical, there should be frequent checks by the laboratory of the hemoglobin, red cell and total protein values. If the blood levels and the patient's weight can be maintained, healing is greatly facilitated.

Infection. Infection can produce serious complications. Every burned wound is contaminated and when there is a break in the integrity of the epithelium infection may become invasive and be disastrous.

All of the factors which are necessary for bacterial growth are present in a burned wound. There is contamination, dead tissue, body moisture and body heat. When further bacterial contamination is added to the burned wound, the remaining useful epithelial structures which are necessary for healing of an incomplete thickness burn can be readily destroyed. Further, the presence of infection can create a more profound wound defect. Infection excites a greater response from the wound in that a much more rapid outpouring of protein and fluid will occur, thereby compounding the problem of fluid loss. When a burn is first seen it is contaminated and it is necessary to prevent this wound, at all costs, from becoming infected. Therefore, careful aseptic care must be practiced throughout, from the time of the initial local care until the wound is healed. Pyogenic bacteria are the most common invaders. Frequently, there is a mixed variety of bacteria present in these wounds. Septicemia is a frequent cause of death in patients with extensive burns.

One of the most potent sources of cross-infection is that of dressings done carelessly without due precaution against contamination. When large wounds are exposed to the air in a ward or dressing room, there is

the ever-present danger of bacteria being carried to the wound from the dust and draughts of air. It is imperative to take all precautions to avoid adding infection from this source.

Tetanus is not an uncommon complication in burns. Tetanus immunization must be given to all burned patients. If toxoid has been previously administered, a booster dose is all that is required. If doubt exists as to previous immunization with toxoid, then tetanus antitoxin should be given.

The systemic use of antibiotics in burned patients is a much debated problem. Too frequently the antibiotics are administered routinely when they are not necessary. Unless there has been poor first aid, some delay in the initial care, or if the burn presents a complicating factor such as lung involvement, or burns of the perineum, antibiotics should not be routinely administered. The use of proper antibiotics should be reserved either for definite complications or for short intervals as when burn eschar is removed or skin grafting is performed. Resistant infections due to *Staphylococcus aureus*, coagulase-positive microorganisms, are being reported frequently and can reach epidemic proportions. This type of infection is mainly due to a breakdown of aseptic technique and a blind reliance upon antibiotics to prevent wound infection. Obviously, a chronically infected burn demands antibiotic therapy. However, this should not be instituted until a culture has been made and the sensitivity of the bacteria to the various antibiotics has been demonstrated.

The local application of antibiotics or antiseptics to an open wound has not proved to be the solution for the problem of infection. Too frequently one is prone to rely on a drug to clean the wound in preparation for surgery. This is not wise, for it is well known that the routine local use of a drug greatly increases the resistance of the bacteria and the sensitivity to it.

Initial Treatment of the Burned Wound. The objective of the care to be given to the burned patient is the immediate cleansing and protection of the wound and the repair of the systemic alteration resulting from the burn shock state. Initially a burn is very difficult to assess accurately as to depth or extent. Therefore, the wound must be protected and attention directed to care of the burn shock. After a few days, an accurate estimation of the extent and depth of the burn can be determined. The problem in burns is identical to that of any traumatic

wound, namely, the conversion of the open contaminated wound into a clean closed wound as rapidly as is practical for the patient. In burns, skin grafting is often demanded in closure of the wound.

First aid for a burn can be very simple in civilian practice, for all that is required is to protect the wound carefully and to transfer the patient immediately to a hospital where facilities are available for complete care. The application of home remedies, such as ointment, butter and lard, too often adds further delay and always adds unnecessary contamination. The use of proper antibiotics should be reserved either for definite complications or for short intervals as when burn eschar is removed or skin grafting is performed. Resistant infections due to *Staphylococcus aureus*, coagulase-positive microorganisms, are being reported frequently and can reach epidemic proportions. This type of infection is mainly due to a breakdown of aseptic technique and a blind reliance upon antibiotics to prevent wound infection. Obviously, a chronically infected burn demands antibiotic therapy. However, this should not be instituted until a culture has been made and the sensitivity of the bacteria to the various antibiotics has been demonstrated.

The local application of antibiotics or antiseptics to an open wound has not proved to be the solution for the problem of infection. Too frequently one is prone to rely on a drug to clean the wound in preparation for surgery. This is not wise, for it is well known that the routine local use of a drug greatly increases the resistance of the bacteria and the sensitivity to it.

Initial Treatment of the Burned Wound. The objective of the care to be given to the burned patient is the immediate cleansing and protection of the wound and the repair of the systemic alteration resulting from the burn shock state. Initially a burn is very difficult to assess accurately as to depth or extent. Therefore, the wound must be protected and attention directed to care of the burn shock. After a few days, an accurate estimation of the extent and depth of the burn can be determined. The problem in burns is identical to that of any traumatic

wound, namely, the conversion of the open contaminated wound into a clean closed wound as rapidly as is practical for the patient. In burns, skin grafting is often demanded in closure of the wound.

First aid for a burn can be very simple in civilian practice, for all that is required is to protect the wound carefully and to transfer the patient immediately to a hospital where facilities are available for complete care. The application of home remedies, such as ointment, butter and lard, too often adds further delay and always adds unnecessary contamination. Simple protection by the use of the cleanest available material to exclude the air is the most practical type of first aid.

Immediately upon admission to the hospital, the patient should be quickly assessed as to the type and, roughly, the extent of the burn. Many minor burns do not demand hospitalization nor will the patients exhibit shock, but, when the burned area is larger than the "flash burn" regions, in all probability hospitalization will be required and burn shock may be anticipated.

The initial care of the burn is performed without the use of anesthesia. For those with extensive burns, anesthesia is contraindicated because of its deleterious effect on the accompanying burn shock.

Narcotic drugs are not routinely administered to the acutely burned patient. If pain is a factor, a small dose of morphine may be given intravenously. In patients with burn shock, the subcutaneous injection of morphine is dangerous and useless. In these patients, the drug cannot be absorbed until the circulatory deficit has been corrected. If repeated doses have been given, morphine poisoning can occur with the return of circulatory efficiency. Restlessness is a symptom of severe burn shock and is not an indication for a narcotic. Pain can be greatly diminished if the local care is undertaken in a room which is moderately warm and where draughts of air can be avoided.

Under aseptic conditions, the burned site and the area well beyond it in all directions are gently cleansed with large pledgets of sterile cotton that have been dipped in a mixture of bland soap and warm sterile water. The wound is carefully flushed and all obvious blebs and loose bits of skin are removed. The procedure can be done carefully and yet rapidly. It is remarkably painless if gentleness is practiced and sterile water at body temperature is used for washing and flushing.

A single layer only of sterile, fine-mesh

gauze is placed over the wound and the entire area is then covered with a previously prepared dressing. The fine-mesh gauze may be impregnated with a light coating of petrolatum prior to its sterilization. This is held in place by some form of bandage which produces a uniform compression dressing. The compression dressing must not be tight, and must have a definite amount of resiliency. If the burn involves an extremity, immobilization is secured by applying a splint. When the wound is covered and air is excluded, there is almost complete absence of pain.

Every hospital or first-aid station should be equipped with previously prepared sterile dressings always in readiness for burned patients or extensive open injuries. These dressings are made with 24-ply Cellucotton with fine-mesh gauze attached to one side. They are made in two sizes, one suitable for small burns or burns of the hand and forearm, the other sufficiently large for either the posterior or anterior trunk, or to encase the entire lower extremity of an adult. These stored sterile dressings can be taken out quickly and applied rapidly. They are useful not only for emergency local care of the wound but also in later care if skin grafting is required. The dressings are of sufficient thickness to allow uniform compression to the open wound.

The petrolatum-impregnated gauze is used only to permit ease of removal later; it is merely a mechanical agent and has no healing power. At the time of removal, the gauze should be gently lifted away to minimize tearing of the new epithelial layers.

The dressings are usually not disturbed for from five to eight days unless there is indication that they should be restored.

The initially applied burn dressing may be useful in most areas except the face and the perineum. These regions are usually left exposed.

One of the rediscovered methods of local care is that which is termed "exposure." This method relies on exposing the burned wound to the atmosphere and its value lies in drying of the wound which reduces the possibility of infection. It eliminates the necessity of dressings, but, in order to be successful, excellent nursing care and a thorough understanding and ability to cooperate on the part of the patient are required. The dry crusts are allowed to remain in place until epithelization has occurred, permitting the crusts to be lifted away.

Exposure of a burned area is initially pain-

ful and drugs are, therefore, necessary to control this pain. This use of drugs may at times confuse the clinical picture of burn shock. Without excellent nursing care, the exposure method is impractical for burned children and is difficult in all patients with an encircling burn of an extremity or of the trunk. However, in encircling burns it can be used if the patient is turned frequently during the first few days to aid in the drying process. The method cannot be used for burns complicated by open injuries. Finally, it is of value only during the early period of treatment, for after five to eight days, when a whole thickness burn is evident, removal of the slough and a compression dressing over this burned region are demanded. Exposure has no place in the treatment of raw open wounds and, therefore, when such a wound is apparent this method must be abandoned. Briefly, then, unless the burn is superficial, the exposure method is of value only during the first few days or the early phases of a burn.

Later Care of the Burned Wound. After five to eight days, it is entirely logical to inspect the burned wound. It is seldom necessary to use an anesthetic for the redressing procedure. Since at this time nothing will be gained by complete removal of the entire dressing, only the outer prepared dressing is removed and the initial fine-mesh gauze is not disturbed. It is actually harmful to remove the gauze initially placed next to the wound, for this will only add trauma to the surface and may tear away the healing epithelium. It is possible to see the wound through the single layer of fine-mesh gauze and to determine the true extent and depth of the burn after five to eight days. At this time the burned wound is well demarcated, both as to extent and depth, and it is obvious if it is of third degree. The burn of incomplete thickness, or second degree, is dry and epithelization is beginning from the hair follicles and sweat glands. The whole thickness or third degree burn will show alterations of color and a depressed eschar, which is anesthetic, beneath the surrounding skin level. The edges of the whole thickness eschar or slough may be moist. The state of the wound can be determined by careful inspection.

If the burn is superficial or partial thickness in character or if there are scattered small whole thickness burn areas, it is then wise and proper to simply re-apply a fresh sterile compression dressing over the undis-

turbed initially placed single-gauze layer and to continue this protection of the wound until complete healing has occurred. If the character of the wound is estimated correctly, healing is accomplished within ten to fifteen days. However, when there is whole thickness loss of skin the surgeon must decide in what manner to remove this slough and how best to convert the resulting open wound into a closed wound. The slough of a third degree burn may involve skin, subcutaneous tissue, muscle, fascia, tendon and bone, but this in no way alters the principle or the necessity for removal of the dead mass. A whole thickness burn evokes a foreign body type of reaction and the host tries to sequestrate the dead tissue. Infection is not common five to eight days after injury in a well treated burn. The secretion emanating from the edges of the slough simply represents liquefaction of the debris.

Removal of the whole thickness burn slough should be accomplished early and may be performed in one of various methods:

Under the most scrupulous aseptic technique, the wound is redressed and the dead material is cut away daily. This method is time consuming, the patient experiences considerable pain and daily dressings are required for maximal efficiency. There is an ever-present danger of adding infection or establishing a cross-infection by this technique. The method is satisfactory, however, in patients with burns of the face, where the blood supply is very rich and sequestration occurs rapidly. It is possible to start dressings and removal of the slough of the face in five to eight days following the injury so as to have the open wound in readiness for grafting by the tenth to fourteenth day.

Chemicals, such as pyruvic acid and acetic acid, have been used for removal of the burn slough. There are also various enzymatic drugs which can digest the dead tissues. These drugs and associated remedies are effective only in superficial deep burns. However, when the burn slough involves fascia or deeper tissues, these agents are not efficient and frequently do not penetrate to the undersurface of the eschar to aid in digesting the collagen fibers. The principal advantage of these agents is that they can be applied easily. However, they are not always effective in accomplishing the desired result and often there is pain associated in their administration.

Surgical excision is an ideal method for removing the larger sloughs of tissue. It should never be used on the face or the neck where there is adequate blood supply which normally produces rapid sequestration. After five to eight days, when it has been proved that whole thickness burn is present and the patient's general condition is at a satisfactory level, in the operating room, with the patient under general anesthesia, the areas surrounding the wound are gently cleansed and with sharp dissection the necrotic tissue is removed. This is not a "block dissection" of the mass. It is properly a surgical excision and only the obvious dead tissue is removed. The dissection follows not only the irregular contour of the burn edges but also the irregular depth of the wound. When the dissection is performed between five and eight days after injury, the surgeon will follow a line of edema in which there is minimal bleeding. If the dissection is too deep, bleeding will occur, which signifies unnecessary removal of healthy tissue. All tissue must be saved when there is reasonable doubt of its involvement. Recently the removal of eschars has been facilitated by using the electric dermatome to remove the necrotic skin. This has to be done prior to the stage of extensive autolysis of the burned tissue. When the resulting open wound is extensive, then it is wisest to cover the wound with a large previously prepared sterile dressing and obtain compression over the wound. No ointment or drug is applied. The patient is returned to his bed and forty-eight hours later, after the blood levels have been restored, he is returned to the operating room where skin grafting or skin dressing is performed.

When the wound is inspected forty-eight hours after surgical excision, there may be small areas which show that the entire burn slough has not been removed. This is not to be considered a fault, but rather that conservatism was used at the time of excision. It is entirely possible to remove these small areas of deeper slough at this time and to proceed with closure of the wound by skin grafting. In localized burns of the hand or of the foot, it is entirely possible to control adequately the oozing and hemorrhage and immediately to skin graft the wound and perform closure at the time of excision.

Regardless of the method used to dissect the whole thickness eschar, it is imperative that the necrotic mass be removed before the wound becomes severely infected and

before the continued and increasing wound discharge depletes the patient's protein reserves to a dangerously low level. Procrastination in waiting for spontaneous separation of the slough, or reliance on some particular drug to accomplish this, jeopardizes the progress of the patient. Too often extensive burns appear to be in excellent condition in ten days, in fair condition in twenty days and in critical condition in thirty days. This clinical picture is the result of the continuing progress of deterioration due to the loss of protein, weight loss and secondary anemia. Every effort should be directed to the conversion of the burned wounds into closed wounds between the second and third week, when at all practical, for it is at this time that the patient has the ability to heal and to respond to such therapy.

Autogenous skin is essential for the permanent coverage of large full thickness burns. However, in extensively burned patients homografting of skin may be a life-saving measure. Fresh cadaver homografts can be used to cover temporarily a large raw surface, particularly when the wound is clean and ready to receive skin grafts and when the available donor areas will not yield sufficient autografts to close more than a fraction of the open wound. The homografts will slough in about three weeks but halt the profuse loss of protein and blood from the large open surface during that time. Meanwhile, if the patient's donor areas heal without infection, these areas may be re-used to obtain more autografts. It is not uncommon to use the same donor area three or four times to obtain successive crops of skin during the course of treatment of the patient with extensive full thickness burns. Donor sites are comparable to partial thickness burns. If infection and irritation are avoided and thin grafts are taken, the donor site heals within two weeks.

In extensively burned patients, certain regions should take precedence in the application of available autografts. The full thickness burns over joints, hands, feet, ears and the face should be covered with skin as soon as possible. In large burns on the trunk, thighs, arms and legs the skin grafts are often applied in postage stamp size. The grafts proliferate and frequently coalesce. For smaller burns in which donor areas are plentiful, the wound should be closed by applying wide strips of skin. The skin grafts are placed in a direction paralleling the natural skin creases, particularly over joints.

If infection has occurred, the granulations become pale and exuberant. The patient's general condition is poor and is reflected in the appearance of the wound. To prepare such a wound for grafting demands aseptic care with moist daily dressings to encourage drainage of the wound. Cultures of these wounds should be taken to determine the exact type of the bacteria and the proper antibiotic to be administered. Before grafting, it is necessary to restore the patient's blood to a high normal level.

The discussion of chronic burns is an admission of failure to heal burns during their normal progress. No well treated burn should become chronic. It is simply delay and procrastination in allowing the patient's general condition to deteriorate and the wounds to become infected. Too frequently, reliance upon the effectiveness of a locally applied drug and failure to have a program of care are the causes for burns coming into a chronic state.

Special Treatment. The treatment of burns in infants and elderly patients requires special care. The infant shows a marked shock state which can vary considerably from hour to hour. This is due to the smaller blood volume, which with even minimal dehydration can produce astounding symptoms. The principles of care for shock are identical to those for adults, but the volume of fluid administration must be more carefully observed and the surgeon must be content with a urinary output in proportion to the patient's size. Skin grafting on infants and young children is not complicated except for the problem of the thinner donor skin. Fortunately, children tolerate these operative procedures remarkably well. In the aged, the problem is one of being constantly aware of the potential of overloading the cardiovascular system during the shock state. At this time it is wise to keep these patients on the "dry side." Constant careful observation of the urinary output and checking of the lung fields is mandatory. One should be content with a smaller, but steady, urinary output than might be desired in a younger, healthier adult. In the elderly patient, 20 to 30 cc of urine per hour should be considered satisfactory. Elderly, burned patients often have organic disease, renal, cardiac or hepatic, which must be treated concomitantly. Finally, an elderly patient's nutrition may not be at a normal level and these patients need correction of any nutritional problems before surgery is attempted. Elderly persons

do not have reserves of fat and protein to draw upon for healing.

Burns of the face are common but fortunately are seldom as deep as those seen elsewhere on the body. At the time of injury, the patient at all costs automatically attempts to protect the face. The face has an excellent blood supply and will rapidly sequester a whole thickness burn. Separation of the whole thickness slough of a facial burn starts about the fifth to eighth day following the injury and is accomplished by daily cutting away only the obvious slough followed by the application of sterile dressings. It is possible to prepare these wounds for closure by the tenth to fourteenth day following the injury, as grafts take very readily on such an area.

Flame burns of the face should always be a warning that one should anticipate involvement of the upper respiratory tract. Inhalation of noxious fumes, hot air and gases can and does occur, producing marked swelling and edema of the entire respiratory tract. Whenever severe respiratory damage is suspected, a tracheotomy is necessary to save life. The clinical symptoms of impending respiratory obstruction may be sparse. There is often moderate edema of the tongue, but seldom is the voice greatly altered. The patient may frequently have a continuous dry, hacking cough. Unfortunately, respiratory obstruction is not revealed immediately and it is not until some time has elapsed, usually six to eight hours, that it becomes apparent. Cyanosis, air hunger and rapid respirations are the signs of established respiratory difficulty. When these are present there should be no further procrastination, an immediate tracheotomy is indicated. Serious burns of the face usually involve the neck and the physician is confronted with a tense, swollen neck through which he must very quickly reach the trachea to perform the tracheotomy.

Burns of the hand are a common problem and the principles of care are the same as for burns elsewhere in the body. Initially the burn of the hand should be carefully cleansed. Rings should be removed, the fingers dressed individually and the entire hand placed on a splint to maintain the "position of function," to enable the surgeon to apply uniform compression to the entire involved part. The hand is inspected within five to eight days; if there is frank whole thickness involvement of the skin, or a third degree burn, it is advantageous to remove this whole thickness slough while the pa-

tient is under general anesthesia and with the use of a bloodless field obtained by means of the blood pressure cuff. Skin grafting can be done at this time if the wound is surgically clean and hemostasis is complete. If the burn is of such depth that the fingers are gangrenous, they should be removed at the level of demarcation. The level of demarcation is not transverse to the long axis of the finger but instead is conical in shape; the deeper structures are preserved distally. Burns on children's hands occur more frequently on the palmar aspect, while burns of adult hands are more common on the dorsum. However, regardless of the anatomic site, rapid removal of whole thickness slough and coverage by skin dressing will often prevent small joints and tendons from becoming necrotic. This maneuver is done to salvage tendons and joints; later more satisfactory skin replacement may be accomplished after healing is complete.

Burns of the perineum present a difficult problem of management, particularly in young children and infants. These burns fortunately are most often of the incomplete thickness type, and are often the result of sitting in a bucket of boiling water. The use of a catheter may avoid contamination from urine during the first few days. After each bowel movement, the exposed area is carefully cleansed with soap and water. It is fortunate that most burns at this site heal readily and grafting is rarely necessary. There is a definite resistance of the skin in this area to fecal contamination, but when grafting is required the bowels are thoroughly evacuated.

If the patient is placed in the prone position, the grafted area may be exposed. The exposed skin grafts usually take very well if careful attention is given to the removal of exudates with moistened cotton applicators.

Local Cold Injury

By ROBERT B. LEWIS, M.D.

ROBERT B. LEWIS, an Illinoisan by birth, was educated at the State University of Iowa. He trained in pathology and, after joining the Regular Army Medical Corps, he has devoted his interest to this field. His investigative interests led him into the problems of aviation medicine and, in particular, the damage produced by cold injury. Colonel Lewis is Deputy Chief of Pathology Branch, Allied Sciences Division, U S Army Biological Warfare Laboratories, Fort Detrick, Frederick, Maryland.

Predisposing Factors. The temperature of the body represents a balance between metabolic heat production and heat loss, especially from the skin. Normally the central body temperature (core), representing that of the deep internal organs, is constant at 37.5° C. The temperature of the skeletal muscles and skin (shell) may be one or two degrees cooler than that of the core, particularly in the more peripheral portions of the extremities where the relatively large skin area invites heat loss in excess of the amount conveyed by the blood from the core and that resulting from local tissue metabolism. This difference in temperature between the central and peripheral parts of the body becomes progressively greater during continued exposure to cold and accounts largely for the observation that the fingers, toes, ears and nose are most frequently affected in cold injuries.

It is quite apparent that local cold injury will be most likely to occur under conditions which favor heat loss from the skin surface or inhibit heat supply from within. Conditions which decrease the internal heat supply include those which mechanically obstruct blood flow to the extremities, such as constrictive clothing or other pressure-producing objects. Tight or stiff clothing is especially harmful if individuals must remain in cramped quarters with arms and legs flexed. Pressure in the popliteal spaces from the rungs of deck chairs was found to enhance cold injury among bomb shelter occupants during World War II in England.

General hypothermia during cold exposure increases the chances of local cold

injury by decreasing the amount of heat transferred to the extremities by the blood stream. Shock, accompanying injury, operates in the same manner.

It has been stated that fatigue and malnutrition predispose to cold injury, but the importance of these factors remains to be determined. It is conceivable that malnutrition, sufficiently severe to decrease caloric production appreciably, might enhance the development of cold injury.

The most important predisposing factors have to do with increasing tissue heat loss. Wind blast was a prominent feature leading to the development of cold injuries in high altitude bomber crew members during the early part of World War II. On the ground, lesser cold breezes favor the development of cold injury. In either case, the movement of cold air removes the warm layer of insulating air from around the exposed parts. When water or metal replaces air as the medium surrounding cold-exposed parts, cold injury is more apt to occur than when air is the medium since water or metal conducts heat better than does air. For this reason, persons with wet feet develop injury at considerably higher temperatures than those exposed in cold dry air. Contact of the skin with cold metal can produce almost instantaneous freezing of tissue.

Environmental protection, including shelter and the quality and quantity of clothing, has a profound effect upon the development of cold injuries. Wet clothing is especially dangerous.

There is considerable variation in individual susceptibility to cold which can be

altered by acclimatization and training and is related to alterations in peripheral blood flow.

For reasons which are not clear, tissues which have been injured by cold are thereafter particularly sensitive to low temperatures.

Some surveys in the military service suggest that Negroes are more susceptible to cold injury than Caucasians. However, this impression may be erroneous because of differences in factors such as education, training and motivation rendering the sample groups nonhomogeneous.

It has not been possible to correlate the presence or levels of blood cold agglutinin titers with the incidence or extent of cold injury.

Classification. It is customary to name cold injuries according to the physical conditions prevailing when the injuries are incurred. Thus, the term "trench foot" is applied to cold injuries occurring in personnel occupying trenches in cold wet climates, and similar injuries developing in shipwrecked mariners, whose extremities have dangled in cold or cool water for hours or days, are called "immersion leg, foot or hand." Also, "shelter foot" has been applied to cold injuries occurring in bomb shelters. The term "frostbite" has been reserved for cold injuries resulting from the actual freezing of tissues. It must not be construed that these terms represent different degrees of cold injury or even different pathologic processes.

It is desirable and feasible to classify cold injuries on the basis of severity regardless of the manner in which they are incurred, in much the same way as are burns. Such a classification includes four degrees of injury which are in the order of increasing severity as follows:

Numbness, swelling, and erythema, without vesiculation. Superficial desquamation in some cases.

Partial skin thickness vesiculation.

Involvement of entire thickness of skin and varying depths of subcutaneous tissue.

Involvement resulting in loss of the part.

Pathology. The pathologic changes resulting from freezing injuries (frostbite) and nonfreezing injuries (trench foot or immersion foot) are identical, although generally a greater volume of tissue is involved in the latter.

The abnormalities produced in the local blood vascular system and other exposed tissues are the same as observed in burn

injuries except that incineration of tissue may occur in the latter.

The fact that freezing and nonfreezing injuries are the same pathologically, and that both may or may not result in gangrene, brings out the point that it is not the attained tissue temperature that will determine the final injury, but rather the product of temperature and exposure time. Of course, the surrounding conducting medium, whether it be air, water, or metal, will affect this product appreciably.

It has been shown experimentally, by covering exposed parts with rubber boots during immersion, that water merely acts as a thermal conductor in the production of immersion type injuries. Maceration of the skin, commonly observed in this type injury, should not be considered as being due to cold but as something caused by the local effects of moisture.

The various fixed tissues do not show the same degree of susceptibility to cold injury. Nerves and striated muscle are highly susceptible; skin, fascia and connective tissue are quite resistant but not as resistant as compact bone or tendon. Blood vessels are highly susceptible to injury resulting in leakage of plasma into the surrounding tissue, but it is important to know that they are relatively resistant to cold-induced necrosis. This difference in tissue susceptibility has resulted in the observation, in both human beings and experimental animals, of muscle gangrene without necrosis of the overlying skin following cold exposure, thus producing a closed lesion.

The great majority of cold injuries are of the nonfreezing type and are generally associated with wetness with the ambient temperatures several degrees above freezing. Immersion of extremities in the South Atlantic Ocean at temperatures considerably above freezing (60 to 70° F.) for days or even weeks produced serious cold injuries, often with gangrene, during World War II. Actual solidification of tissue from freezing has been observed relatively rarely. Probably in most persons with so-called frostbite incurred during exposure to dry air at below-freezing temperatures, actual freezing of the extremities has not occurred. Under such conditions of exposure, the body can defend against the cold quite effectively in spite of steep temperature gradients existing between the body and the surrounding atmosphere because air is a rather good thermal insulator. Prolonged exposure may thus be endured without resulting in tissue

solidification although sufficiently severe chilling of the parts does occur to produce damage.

Supercooling of tissues has been observed in both skin and muscle. By this process, tissues are cooled considerably below their freezing temperatures (-2.2° to -2.5° C) without ice formation. Its significance is not known.

Intracellular or extracellular ice crystal formation apparently is not an important factor in the production of cold injuries. The freezing of tissues does not necessarily result in gangrene and cell death can occur from exposures to temperatures above freezing.

Blood vascular system. It has been determined that an ambient air temperature of 16° C (61° F.) usually results in loss of skin heat, especially in those areas where the ratio of surface area to tissue mass is high, namely, in fingers, toes, ears and nose. The heat loss is controlled by changes in the cutaneous blood vessels as follows: a direct effect of the cold resulting in constriction of the vessels, a temporary generalized vasoconstriction initiated through central nervous system action and a persistent constriction of the vessels resulting from cooled venous blood acting on the central vasomotor centers. Arteries, arterioles, capillaries, venules and veins participate in these reactions. The purpose of these vascular responses is to conserve body heat, but by so doing the peripheral parts are made more liable to cold injury as the exposure conditions become more severe, since obstruction of blood flow to a part enhances tissue cooling. This apparent paradox is a process of sacrificing a part for the good of the whole.

It has been observed that, following the drop in skin temperature of a part during cold exposure, there may be periodic elevations of temperature of as much as 16° C., caused by periods of vasodilatation. This mechanism, called "hunting," is an attempt to keep the peripheral tissues warm while at the same time trying to maintain the core temperature.

After thawing of frozen parts or warming of tissue after prolonged severe chilling, blood flow begins in the capillaries which become dilated. Stasis begins immediately and becomes complete in some ten minutes. After stasis has rendered the capillaries non-functional, blood flow occurs in arterio-venous anastomoses and in arteriole-venular capillaries. As stasis develops, fluid is

lost through the injured capillary walls and the stranded red blood cells become packed together in masses to form what has been called sludges. The edema, which is mostly subcutaneous, becomes maximum about six hours after warming and begins to subside after approximately twenty-four hours. Before resorption is complete, organization of the edema fluid tends to occur, forming adhesions between the skin and the underlying muscle fascia.

The blood flow increases after warming of cold-injured parts as determined by direct blood flow studies or indirectly by tissue temperature measurements, although such determinations do not inform us of the course the blood takes through the tissues.

The question of the role played by these vascular reactions in the production of cold injuries, including gangrene, cannot be answered with certainty. These same changes, including the initial vasoconstriction, occur in burn injuries so it would seem that the same significance should be attached to the local blood vascular abnormalities in both types of thermal injury. They probably are of minor importance compared to the direct effects of cold on tissue cells, but certainly vasoconstriction during exposure may secondarily enhance the injury by restricting the heat supply to the parts.

It is significant that living tissue can be killed by cold exposure without benefit of a vascular supply as has been accomplished with tissue cultures.

The similarity of the vascular abnormalities, as well as the identical histologic tissue changes and even the same clinical manifestations as are observed in both cold and heat injuries, suggests that both have the same pathogenesis and are true thermal injuries.

After the acute stages have passed, arteries and arterioles may develop fibroblastic proliferation of the intima with narrowing of the lumen. Fibrous replacement of degenerated smooth muscle in vascular walls with subsequent contracture probably also occurs to decrease further the diameter of vessel openings.

In some cases, the chronic stage of cold injury is characterized by increased warmth of the affected parts even adjacent to gangrenous areas. In others, there are lowered tissue temperatures which have been assumed, but not proved, to be due to overactivity of the sympathetic nerves with persistent vasoconstriction. Further investigations will be necessary to determine

whether the diminished blood flow in these cases is functional or due to organic changes in blood vessel walls.

Thrombosis occurs after twenty-four to thirty-six hours provided the blood vessels are sufficiently injured to produce acute inflammation with or without necrosis of the walls. This thrombosis is a secondary phenomenon which occurs in other types of physical injury rather than being the cause of gangrene.

Skin. Intracellular vacuoles can be observed in the cold-injured epidermis microscopically and are evidence of edema. Necrotic areas of epidermis have been observed as early as two hours after freezing of skin in experimental animals. The gangrene begins in the superficial epithelial layers and may be confined here to produce superficial desquamation with survival of the deeper layers which in the end often become atrophic. The atrophy may either be accompanied by hyperkeratosis or a reduced number of epithelial cell layers. The papillae tend to become flattened. As the intensity of exposure increases, the resulting gangrene becomes deeper until all layers of the skin and subcutaneous tissue become involved. The gangrene is dry unless secondary infection occurs.

Nerve tissue. Relatively mild cold exposures result in immediate functional disturbances of nerves characterized by sensory loss and muscle weakness or paralysis. This latter may be due to a combination of nerve and muscle injury. More severe exposures produce edema of nerve fibers, granular degeneration of myelin sheaths and swelling or degeneration of axis cylinders.

The rapidity with which muscular paresis or paralysis occurs immediately following exposure in experimental animals can only be explained on the basis of direct cold effects on tissue cells. To be caused secondarily by vascular events such as constriction, dilatation with edema, stasis with sludging of red cells or thrombosis would require a lapse of some time.

Muscle. Muscle shows several pathologic lesions, after exposure to either freezing or nonfreezing cold, which represent different degrees of injury. The least severe lesion is simple atrophy in which the fibers are reduced in size but maintain their form. Muscle atrophy has been a frequent and persistent sequela of World War II cold injuries.

A little more intense exposure results in slow muscle cell death within a few days.

The cells degenerate beyond simple atrophy so that they eventually waste away and die and are replaced with scar tissue. Often such dying fiber fragments show hypernucleation which apparently represents a futile attempt at cell reproduction. This type of slow cell death has been called "degenerative atrophy" in the older literature to distinguish it from simple atrophy, but "slow necrosis" would seem a preferable term.

The most severe muscle change is coagulation necrosis and represents acute cell death. The fibers are swollen, homogeneous and, as a rule, show loss of cross-striations. In some instances, the cross-striations are more prominent than is normal. This lesion can be observed as early as fifteen or thirty minutes after severe local cold exposure in experimental animals.

Observation of acute necrosis in so short a time does not support the vascular theory of cold-induced gangrene since complete tourniquet-induced ischemia must act for about three hours to produce like changes. Cold must produce metabolic cellular changes in muscle cells by direct action which in relatively mild exposures result in disturbed metabolism leading to atrophy and in more severe exposures lead to cell death either acutely (coagulation necrosis) or more slowly (slow necrosis) (Fig. 4).

These three lesions may be present in the same muscle when conditions of exposure are right and are layered from the cutaneous surface in the order of decreasing severity. Thus, coagulation necrosis is present at the surface with a layer of slow necrosis just beneath and still deeper is to be found simple atrophy. This arrangement is not surprising since the temperatures in an ex-

Figure 4. Tibialis anticus muscle from rabbit sacrificed one week after exposure of a hind leg to an alcohol bath at -36°C . for two minutes, forty seconds. Three degrees of injury are present which are layered from the cutaneous surface in the order of decreasing severity as follows (1) coagulation necrosis, (2) slow necrosis and (3) atrophy; hematoxylin and eosin; $\times 100$.

solidification although sufficiently severe chilling of the parts does occur to produce damage.

Supercooling of tissues has been observed in both skin and muscle. By this process, tissues are cooled considerably below their freezing temperatures (-2.2° to -2.5° C.) without ice formation. Its significance is not known.

Intracellular or extracellular ice crystal formation apparently is not an important factor in the production of cold injuries. The freezing of tissues does not necessarily result in gangrene and cell death can occur from exposures to temperatures above freezing.

Blood vascular system. It has been determined that an ambient air temperature of 16° C (61° F.) usually results in loss of skin heat, especially in those areas where the ratio of surface area to tissue mass is high, namely, in fingers, toes, ears and nose. The heat loss is controlled by changes in the cutaneous blood vessels as follows: a direct effect of the cold resulting in constriction of the vessels, a temporary generalized vasoconstriction initiated through central nervous system action and a persistent constriction of the vessels resulting from cooled venous blood acting on the central vasomotor centers. Arteries, arterioles, capillaries, venules and veins participate in these reactions. The purpose of these vascular responses is to conserve body heat, but by so doing the peripheral parts are made more liable to cold injury as the exposure conditions become more severe, since obstruction of blood flow to a part enhances tissue cooling. This apparent paradox is a process of sacrificing a part for the good of the whole.

It has been observed that, following the drop in skin temperature of a part during cold exposure, there may be periodic elevations of temperature of as much as 16° C, caused by periods of vasodilatation. This mechanism, called "hunting," is an attempt to keep the peripheral tissues warm while at the same time trying to maintain the core temperature.

After thawing of frozen parts or warming of tissue after prolonged severe chilling, blood flow begins in the capillaries which become dilated. Stasis begins immediately and becomes complete in some ten minutes. After stasis has rendered the capillaries non-functional, blood flow occurs in arterio-venous anastomoses and in arteriolar-venular capillaries. As stasis develops, fluid is

lost through the injured capillary walls and the stranded red blood cells become packed together in masses to form what has been called sludges. The edema, which is mostly subcutaneous, becomes maximum about six hours after warming and begins to subside after approximately twenty-four hours. Before resorption is complete, organization of the edema fluid tends to occur, forming adhesions between the skin and the underlying muscle fascia.

The blood flow increases after warming of cold-injured parts as determined by direct blood flow studies or indirectly by tissue temperature measurements, although such determinations do not inform us of the course the blood takes through the tissues.

The question of the role played by these vascular reactions in the production of cold injuries, including gangrene, cannot be answered with certainty. These same changes, including the initial vasoconstriction, occur in burn injuries so it would seem that the same significance should be attached to the local blood vascular abnormalities in both types of thermal injury. They probably are of minor importance compared to the direct effects of cold on tissue cells, but certainly vasoconstriction during exposure may secondarily enhance the injury by restricting the heat supply to the parts.

It is significant that living tissue can be killed by cold exposure without benefit of a vascular supply as has been accomplished with tissue cultures.

The similarity of the vascular abnormalities, as well as the identical histologic tissue changes and even the same clinical manifestations as are observed in both cold and heat injuries, suggests that both have the same pathogenesis and are true thermal injuries.

After the acute stages have passed, arteries and arterioles may develop fibroblastic proliferation of the intima with narrowing of the lumen. Fibrous replacement of degenerated smooth muscle in vascular walls with subsequent contracture probably also occurs to decrease further the diameter of vessel openings.

In some cases, the chronic stage of cold injury is characterized by increased warmth of the affected parts even adjacent to gangrenous areas. In others, there are lowered tissue temperatures which have been assumed, but not proved, to be due to overactivity of the sympathetic nerves with persistent vasoconstriction. Further investigations will be necessary to determine

eventually become mummified. The final line of demarcation between living and dead tissue generally does not become sharply delineated for about a week to ten days.

In somewhat less severe injuries, desquamation of epidermal casts of involved fingers or toes, including the nails, may occur or even shedding of practically the entire soles of the feet.

When large volumes of tissue have been involved, as in immersion type injuries, muscular paresis or even paralysis may ensue, depending on the severity of exposure.

Some patients develop anhidrosis of the cold-injured areas, whereas others show hyperhidrosis with or without concomitant maceration of the skin.

The persistence of signs and symptoms and their severity depend on the degree of injury. Patients with mild cases recover completely, whereas those having severe ones tend to develop disabling sequelae. Some of these latter patients show hyperhidrosis, low skin temperatures (accentuated by the evaporation of sweat) and cyanosis, and others present manifestations of peripheral nerve involvement, but the majority have a mixture of these two types.

Contrary to popular opinion, a considerable number of patients with late cases show normal plethysmographic recordings and as warm, or warmer, skin temperatures in the more severely injured areas.

Those with the nerve type show tenderness over the metatarsal-phalangeal portion of the foot with aching or sharp shooting pains which radiate toward the ankle. Pain on weight-bearing areas of lower extremities makes walking extremely difficult. Many have areas of hypesthesia to pin prick and cotton, whereas others show hyperesthesia.

Persistent ulcers on the feet develop at times and heal with difficulty.

Hyperextension of the toes, especially of the great toe, occurs in some cases in the chronic stage and represents contracture of fibrosed muscle.

Treatment. Therapy should be divided into that of the cold injuries per se and of the late sequelae. The former can be further divided into initial, or first-aid, and hospital treatment.

Rest of the parts is essential. Involved upper extremities should be placed in slings and persons with lower extremity involvement should be transported by litter. Walking on cold-injured feet only serves to aggravate the damage. Massage or rubbing of the cold-injured parts should be avoided.

The local application of snow or other means of cooling has no place in the treatment.

At the earliest practicable time, efforts should be directed toward the return of the local tissue temperatures to 37.5° C. without overheating the tissue. This should be done even though the parts are thawed but still cool. Probably the most efficacious and safest way to accomplish this is by immersion of the cold-injured part in warm water. The temperature of the water should not exceed 42° C. (107° F.) and the time of immersion should only be sufficiently long to return the tissue temperature to normal. Anesthesia may be required to control pain during the procedure.

After the tissue has been brought to normal temperature, the injured parts should receive the same supportive care as they would following any other physical injury. Complete bed rest is important until the degree of damage can be ascertained and it should be continued if blebs or gangrene develop.

Strict asepsis must be adhered to in the handling and dressing of cold injuries. As a prophylaxis against secondary infection, penicillin (a minimum of 300,000 units daily) should be administered to all second, third or fourth degree injuries. When secondary infection becomes apparent, isolation of the offending organisms should be accomplished and sensitivity tests performed to determine the desirable antibiotics or sulfa drugs for use in each case. Infection with *Pseudomonas aeruginosa* is not uncommon and is very resistant to ordinary treatment but has been found to respond favorably to Sulfamylon or polymyxin therapy. Sulfamylon applied topically as an ointment at 5 per cent strength has proved effective.

Blebs should be left intact or, if they break spontaneously, careful superficial débridement is indicated.

Prophylactic tetanus antitoxin, or a booster toxoid injection for those previously immunized, is indicated for patients with broken skin.

Slight elevation of the extremities assists the disappearance of edema, but too great elevation results in disturbed circulation and is to be avoided.

Provided the skin is intact without vesicles, dressings are not necessary. In the more severe injuries, loose dry gauze dressings may be applied and a cradle to prevent contact with bed covers is advantageous. A room temperature of 70° to 78° F. is satis-

Figure 4. Tibialis anticus muscle from rabbit sacrificed one week after exposure of a hind leg to warm water at $+32^{\circ}\text{C}$. for six minutes. The same lesions, occupying the same relative positions, are present as in Figure 4; hematoxylin and eosin, $\times 87$

tremity during cold exposure decrease with depth following an exponential curve. This same picture can be produced by controlled exposure to heat (Fig 5).

Acute inflammatory exudate appears in the areas of muscular necrosis four to six hours after exposure. Fibroblastic replacement of dead muscle begins in about twenty-four hours and is complete in a week. Within thirty-six to forty-eight hours, myriads of macrophages invade the gangrenous area to remove the dead muscle cells and the acute inflammatory exudate recedes.

Bone, cartilage and tendon. The marrow of bone is quite sensitive to cold. The cells disappear and a serous-gelatinous mass remains which eventually becomes replaced with connective tissue. Changes in the cortex vary from atrophy to actual necrosis and the former can be observed roentgenographically as demineralization or porosity. The endosteal bone trabeculae show thinning with corresponding enlargement of the marrow cavity and dilatation of the haversian canal system gives rise to a spongy appearance.

Necrotic areas show loss of bone cells and demineralization, the cartilage of joints may be affected with subsequent ankylosis.

Tendon is very resistant to cold injury. Connective tissue including fascia is relatively resistant to cold and shows a remarkable ability to proliferate in the healing phase provided some viable cells survive.

Symptoms and Signs. The seriousness of the signs and symptoms depends not only on the severity of the cold exposure but also on the volume of tissue involved. This latter aspect is very important in immersion type injuries. The clinical picture of so-called frost-bite and immersion type injuries is identical, provided the intensity of exposure (time-temperature product) and the amount

of tissue exposed are the same. This is rarely the case, since the majority of so-called frostbite injuries involve parts of fingers or toes, whereas immersion type injuries affect much larger areas. Under such circumstances, the signs and symptoms are qualitatively but not quantitatively similar. However, reports are to be found in the medical literature pointing out identical clinical manifestations in the two types of cases. There is, therefore, no more reason to describe freezing and nonfreezing injuries separately than to differentiate between the local signs and symptoms of small and large area burns.

Exposure to local cold is as a rule not a painful experience in either freezing or non-freezing cold injuries. The afflicted individual becomes aware of coldness of the exposed parts and at times has some stinging pain. These symptoms are followed by a feeling of local numbness and, finally, loss of all sensations. In immersion type injuries, the involved extremities feel "dead" or "wooden" and swelling occurs because of injury to capillaries. In freezing injuries, the swelling is delayed until thawing has occurred. At first the color of the skin alternates between white and pink, reflecting the state of the cutaneous blood vessels, but after severe exposure remains pale. On walking, some subjects develop severe "pins and needles" sensations.

During and after warming, the signs and symptoms become more alarming. The parts become red or bluish and feel warm with bounding arterial pulse and are painful. Swelling becomes greater with or without bleb formation in the epidermis. The blebs usually contain clear straw-colored fluid which tends to coagulate because of its relatively high protein content. Hemorrhage may occur within the bullae. Injuries insufficiently severe to cause vesicles or bullae often show superficial desquamation of the epidermis within a few days. Those that eventually develop deep gangrene have a more severe clinical picture than those that escape necrosis.

In some instances, the phase of hyperemia as manifested by local warmth and redness is transient and gives way to coldness and cyanosis. The latter sign is generally accentuated by dependency. Frequently, these patients suffer from burning pain, especially at night.

Within one to three days, parts destined to become necrotic become dark brown and finally black. The areas of dry gangrene

is likely to develop in severely injured areas. Fortunately, of all the patients treated by radiation, only a few will require surgical treatment for the effects of the irradiation.

Causes of Irradiation Injuries. X-rays, radium, radon and radioactive isotopes are the sources of radiation and excessive exposure to these is the cause of the local injury. Alpha particles do not penetrate deeply and therefore exert their greatest effect on the skin and mucous membranes. Beta and gamma rays have more penetrating power.

Beta ray burns of the skin of atomic research workers have been reported. Extensive radiation sloughs have occurred as the result of excessive exposure to gamma rays. Acute or chronic exposure to x-rays, however, is still the greatest cause of local radiation injuries.

Overexposure beyond tissue tolerance may be caused by a single massive dose of irradiation or by the cumulative effect of frequently repeated small or adventitious exposures. Usually, acute radiation burns are caused by a single massive overdosage such as might occur with a prolonged fluoroscopic procedure. Chronic irradiation injuries occur more commonly after lesser but frequently repeated radiation exposures in excess of tissue tolerance. Physicians, dentists and technicians may be exposed unwittingly to adventitious doses of radiation over a prolonged time and develop pathologic changes in the skin of their hands after a lapse of many years.

Often-repeated dosages of irradiation for the treatment of some skin ailments, usually of the dermatitis group, may be followed occasionally by irradiation damage requiring excision and skin grafting. The use of irradiation for the destruction of verrucae, superficial tumors, keloids, hair and scars has resulted in both acute and chronic irradiation damage to the skin. Growing bone and cartilage are extremely vulnerable to irradiation and the treatment of overlying skin lesions with improperly applied irradiation has caused injuries to the underlying bone and cartilage. Although it is not common to remove excess hair by x-ray treatment, many of the patients who had this type of epilation twenty years ago are now showing the signs of chronic irradiation damage.

Radioactive cobalt "bombs" are being used increasingly for therapeutic irradiation of certain cancers which are beyond the surgical therapy. Although arrest of

the cancer may result from such treatment, extensive and progressive radiation damage to deeper tissues has been observed. The problem of closure of the defect after surgical excision of the damaged tissue is far from simple because vulnerable structures such as the pericardium, visceral pleura and neurovascular bundles in the axilla and neck may be exposed.

The administration of heavily filtered gamma particles may cause serious damage to deep structures. Viscera, bone, cartilage, muscle and subcutaneous tissue have been involved. The degree of damage is dependent on the radiosensitivity of the tissue, the dosage of the radiation and the amount of absorption by overlying tissue.

The first report of human damage from atomic radiation appeared in 1919. Although the hazards of working with atomic radiation are well known and extreme precautions are taken, accidents can and do occur. With the increasing employment of atomic radiation for military, research and industrial uses, acute radiation burns have to be anticipated.

Pathology of Irradiation Injuries. Irradiation injuries may be either acute or chronic. The first signs of the acute irradiation reaction are indistinguishable from those of other acute inflammatory processes. Sequelae are dependent upon the severity of the dosage and the radiosensitivity of the tissue. Although the majority of acute irradiation burns gradually subside and the skin may resume a fairly normal appearance, the injury causes damage which is progressive even though the course may take many years to become clinically apparent.

The essential pathologic processes in delayed or late irradiation reaction include: alterations in the architecture and cellular composition of the epidermis, obliterative vascular changes in the corium and subcutaneous tissues, necroses in the corium leading to stromal changes and partial or complete destruction of the skin appendages.

In the usual case, the epidermis exhibits atrophy with loss of rete pegs. Focal areas of hypertrophy of the epithelium characterized by acanthosis and hyperkeratosis are common. The melanin content of the basal layer of the skin is increased and accounts for the faint brown pigmentation observed commonly in chronic radiodermatitis. Dysplasia and dyskeratosis are prevalent in severe injuries and are the precursors to carcinoma.

The vascular changes probably rival in

factory. The local application of ointment is not indicated except as treatment for secondary infection.

Amputation of necrotic tissue is to be delayed until the final line of demarcation is stabilized, unless severe infection renders immediate amputation desirable. Constricting eschars should be bivalved.

It has generally been recommended, on theoretical grounds, that cold-injured patients refrain from smoking, but experimental evidence does not support the idea that nicotine increases the extent of gangrene following cold exposure.

After the acute phase has passed and healing has begun, care must be taken to avoid or minimize contractures, joint stiffness or ankylosis. Adequate physiotherapy will do much to alleviate these disabling sequelae.

With extensive gangrene, skin grafting of the exposed deep surfaces will shorten convalescence considerably and result in a better epithelized stump.

Except for rapid warming, specific procedures aimed at decreasing the extent of gangrene have given such equivocal results as to be of doubtful value. Thus, vasodilating drugs, pressure dressings, sympathetic block or extirpation and anticoagulants are not indicated.

The treatment of most of the disturbing sequelae is, as a rule, unsatisfactory owing largely to the fact that their pathogenesis has not been determined. Excess sweating may be helped by practicing good foot hygiene and by the introduction of a 1 per cent solution of formalin into the skin by electric current six times daily. Hyperhidrosis, as well as edema, pain and chronic ulcers, has at times been reported to be

successfully treated with sympathetic block or extirpation, but the numerous failures reported suggest that these procedures are of doubtful value or at best should be used only in very carefully selected cases.

Severe pain in the balls of the feet on weight bearing may be alleviated by orthopedic appliances to the shoes, such as the placing of thick leather or rubber in the instep to act as weight-bearing areas.

Irradiation Injuries

By JOHN L. BELL, M.D.

Tissues subjected to excessive irradiation, whether for diagnostic or therapeutic purposes, may develop pathologic changes which require surgical treatment. The sequelae may appear early, delayed or many years following exposures to radiation en-

ergy. Irradiation damage to the skin is more common than injury to deeper structures such as bone, cartilage, muscle and tendon. The clinical and pathologic courses following irradiation injury are progressive and, if the patient lives long enough, carcinoma

gentleness, aseptic surgical care and the avoidance of irritating topical medicaments. Further irradiation or ultraviolet therapy is contraindicated because of the danger of aggravation of the injury. Because acute irradiation burns are painful, the application of bland soothing medicaments may be of value, but local anesthetics are usually not effective. In some instances, sedation and hospitalization may be necessary to help control the severe pain accompanying acute burns. Exclusion of air from the burned surfaces is of definite value in alleviating pain. In burns of the hands and feet, immobilization of the injured part in a functional position and elevation are advocated to aid in the process of repair and the control of pain.

If a single cauterizing dose of radiation has caused a fairly well delineated burn which does not appear to have a chance of healing spontaneously, the area may be excised and a free skin graft applied. One cannot always be certain of the depth of the injury, however, and the take of the skin graft may be jeopardized by inadequate excision of the burn. Excision and closure by suturing are often fraught with breakdown of the wounds.

Following adequate excision, sliding pedicle flaps from adjacent healthy tissue, or the application of pedicle flaps from distant areas, may be necessary to cover defects which expose bone, tendon and joint surfaces.

Treatment of Chronic Irradiation Burns. The surgical treatment of chronic irradiation injuries should be instituted before malignant changes, ulceration and intractable pain occur. It is unfortunate that many patients do not seek surgical care before these changes are prevalent. Surgical therapy for chronic irradiation burns is too often necessary because of malignant changes. The combination of atrophy, telangiectases and keratoses is a forewarning sign of the inevitable development of carcinoma. Adequate excision and repair are the essentials of the proper surgical management for chronic irradiation burns.

Chronic ulcerated areas are usually accompanied by anemia and hypoproteinemia. In chronic irradiation injuries, it is important to correct anemia and place patients on high caloric and protein-vitamin intake before undertaking extensive surgical corrections.

Atrophy and faint telangiectasis may not require treatment if there is no progress in clinical or pathologic changes, but some pa-

tients will seek surgical treatment to improve appearance. In areas of abundant telangiectasis, which are exposed to the possibilities of repeated trauma or to sunlight, early surgical excision is advisable because of the likelihood of detrimental pathologic changes. Surgical excision and repair should be performed while the areas are still in relatively good condition. Because ulceration is invariably accompanied by stubborn infection, the problem of repair following excision of such areas is compounded.

The local application of various drugs has no lasting beneficial effect on the pathologic course of chronic irradiation burns. Further radiation from any source is contraindicated because of the danger of acceleration of the pathologic changes. It has been established that patients with chronic irradiation injuries do not tolerate strong exposures to either sunlight or ultraviolet. Carcinomas resulting from irradiation should not be treated by more radiation of any kind.

The surgeon confronted by an irradiation injury has a complex problem in that it is difficult to determine the severity of the injury by clinical appearance. The surface lesion is not indicative of the degree of deeper involvement in most cases. When excision is contemplated, the problems of repair should be anticipated. Although most superficial irradiation injuries may be surgically excised and repaired by the application of a free skin graft, excision of an apparently superficial lesion may leave exposed avascular structures which require more adequate coverage for restoration of function and appearance. When bone, tendon, viscera or cartilage is uncovered by the excision, a protecting layer of subcutaneous tissue is required in order to preserve function. Pedicle flaps of whole thickness skin and subcutaneous tissue are fashioned from adjacent healthy tissue or from distant areas to provide necessary coverage in these situations.

Deep necrosis of tissues occurs frequently after intensive radiation therapy for malignant conditions of the chest and neck. Surgical excision of the damaged tissues may be necessary to prevent erosion of large vessels or sloughing of viscera. Closure of the resulting defect may be difficult and should be anticipated prior to excision of the irradiation damage. Pedicle flaps which carry a permanent blood supply to the area may be required to sustain closure and provide adequate protection to the viscera and neurovascular structures.

importance those alterations in the epidermis. Obliterative endarteritis with resulting diminution in blood supply accounts in part for the marked fibrosis and degenerative changes in the stromal elements. Occlusive endophlebitis may be more severe than the arterial involvement and leads to back pressure with the development of telangiectases in the corium.

The early changes in the corium are those of any acute inflammatory process. As vascular changes progress, secondary degenerative changes occur in the stromal elements of the corium. Collagenous fibers become thickened, fibrosed and densely hyalinized. Alterations of elastic fibers are varied, depending on the chronicity and severity of the irradiation damage.

Partial or complete destruction of hair follicles and sebaceous glands takes place in most irradiation injuries. In the milder type, the epilation may be temporary whereas in severe cases permanent alopecia may result. Sebaceous glands are equally or more sensitive than hair follicles to irradiation. Sweat glands have a considerable degree of resistance to radiation and are a good histologic index of the severity of the injury.

Marked dysplasia of epidermal elements should be considered as precancerous lesions. Many subjects show the presence of carcinoma in situ. When invasive carcinoma occurs, it is usually of squamous cell type, although basal cell carcinoma is not uncommon. Distant metastasis can occur with squamous cell carcinoma, but if the invasive process is superficial the extreme fibrosis in the subcutaneous tissue and corium usually holds the carcinomatous cells in abeyance. Wide excision is therefore required in such cases. Extensive local carcinomatous infiltration is commonly observed, especially with basal cell carcinomas. Necrosis of structures deeper than skin and subcutaneous tissue can be produced by the use of large quantities of heavily filtered gamma particles. Radionecrosis of bone, especially the mandible, has occurred, accompanying the treatment of overlying soft tissue malignant disease. The condition called *radiosclerosis* denotes the involvement of dense fibrotic changes in the underlying joint capsules, tendons and muscles without the presence of an overlying skin ulceration.

Clinical Course. Certain pathologic changes occur in the skin in any person subjected to irradiation which proceeds to an erythema reaction. As in thermal burns, the degree of the reaction is dependent

largely on the severity of the dosage and the tolerance of the tissue which is involved. In contrast to thermal injuries, the depth and extent of the irradiation damage are not as apparent in the early stages following the exposure.

Usually, erythema of the skin commences within one to two days after sufficient exposure to alpha particles. This subsides only to reappear in from one to three weeks accompanied by varying degrees of vesiculation, swelling, exudation and desquamation. Pain is an outstanding accompaniment to acute radiation burns.

The degrees to which the pathologic stages advance in the early stages following exposure are dependent on the severity of the injury. These inflammatory signs are characteristic of the acute reaction to single massive overexposures or closely repeated excessive exposures. The acute inflammatory phase may subside gradually, but incomplete repair, leaving the characteristic marks of skin atrophy and dryness, hyperkeratoses and telangiectases, is common. Changes in the pigmentation of the involved area frequently are observed.

In more severe reactions, epilation occurs invariably and may be either temporary or permanent. If the destructive process is of sufficient severity, necrosis and ulceration of the skin ensue. Acute irradiation ulcerations are extremely painful, indolent and often intractable. Persistent, virulent, localized infection is characteristic of irradiation ulcers.

The chronic burn of the skin is characterized by atrophy, telangiectasis and keratosis. In the majority of patients, the scar following irradiation may be inconspicuous and cosmetically acceptable. Previously stable scars, however, have broken down and carcinoma has resulted. Among the factors leading to ulceration of an irradiation scar are slight mechanical trauma, the performance of surgical procedures in the scarred area and the use of further radiotherapy in scarred areas. In chronic repeated exposures to irradiation such as seen in physicians' hands or in patients who have been treated with small doses for acne and other benign skin conditions, telangiectasis takes from three to ten years to appear. Keratosis occurs in ten to fifteen years and carcinoma may take as long as twenty years to appear.

Treatment of Acute Irradiation Burns. Early surgical intervention is seldom necessary or indicated in the management of the majority of acute irradiation burns. The essentials of treatment of the acute burn are

rays emitted by residual radioactivity or by fission products. The syndrome may occur as a result of any sort of atomic explosion: air burst, surface burst or underwater burst of either a fission (conventional A-bomb) or a thermonuclear (H-bomb) weapon or the uncontrolled excursion of a nuclear reactor. In the case of the initial radiation from an air burst or a surface burst, persons who are in the open, unshielded by buildings or natural objects, will constitute the most exposed group at a given distance. Those who are shielded by natural objects or who are in buildings made of brick, concrete or metal will be less exposed and those who are in tunnels, caves or air raid shelters will be the least exposed. It is evident from animal experiments that effective shielding of some portion of the body, such as the spleen, the head, the abdomen or limbs, may reduce the severity of the injury. Only those individuals who were certainly in the open, unshielded, or were in wooden buildings, can be assumed to have received the maximum dose of initial nuclear radiation which could be expected at a given distance. It is proper to assume that all others have received less than the dose that is theoretically possible. It is apparent that it will not be possible to classify casualties solely on the basis of their distance from the explosion. The severity of the exposure to residual radioactivity and/or fission products will depend upon the degree of contamination of the area and the length of time an individual remains there. In most cases, the dose will not be known with any degree of certainty, although a maximum estimate may be available. In the case of area contamination, members of the group who remain indoors or in shelters will be less exposed than those who remain in the open throughout the time they are in the radioactive region.

On the basis of the study of the Japanese casualties during World War II, and by analogy with other forms of trauma, radiation casualties can be divided into two classes: (1) those with uncomplicated radiation injury and (2) those having radiation injury complicated by burns and wounds. It is not known with certainty how important such complications as the latter may be, but it appears that the effect may be considerable.

Symptoms of Whole Body Radiation Injury. The syndrome of radiation injury due to exposure of the whole body to initial nuclear radiations at the time of an atomic explosion occurs in three fairly distinct

forms. It seems quite likely that exposure to comparable amounts of radiation over a period of ninety-six hours or less, as in a radioactively contaminated area, would cause comparable clinical findings.

Very severe radiation injury occurs when the dose of radiation is in excess of 600 r (or rep, i.e., roentgen equivalent physical). In this form vomiting commences shortly after the exposure occurs and may persist for several days. Progressive malaise leading to prostration begins soon after exposure and these symptoms continue unabated until death. Diarrhea usually appears within a few days and persists. Fever of the continuous type appears within the first few days and increases progressively. Leukopenia is present from the first day and becomes progressively more severe, so that terminally the total white count may be less than 100 cells per cu. mm. Hemorrhagic manifestations, such as purpura, may appear shortly before death, but they do not appear to be responsible for the fatal outcome. Epilation may be noted during the second week. Without therapy, death is inevitable and may occur at any time from the first day to the end of the second week.

Severe radiation injury occurs when the dose of radiation is of the order of $400\text{ r} \pm$ about 200 r (or rep). In this form, vomiting commences shortly after the exposure occurs, but it seldom persists beyond the first day. A latent period follows during which the only symptom is increasing malaise. The end of the latent period occurs during the second or third week after exposure and is marked by the appearance of one or all of the following characteristic symptoms of radiation injury: epilation, purpura, other manifestations of the hemorrhagic state and painful inflammatory lesions of the mouth and throat. Concurrently, a variety of conditions may develop such as diarrhea, infection and the breakdown of healing wounds. The patient rapidly becomes quite ill and has fever and prostration and a severe hemorrhagic state may occur. If death follows it is usually due to acute blood loss, septicemia or hemorrhage into a vital structure. Death may occur at any time between the third and the sixth week after exposure. Lymphopenia is evident from the outset, but the hematologic findings become most pronounced during the third to the fifth week and consist of severe leukopenia, thrombocytopenia and anemia, and prolonged bleeding and clotting time. As recovery occurs the hemorrhagic manifestations subside and spontaneous defer-

Nuclear Radiation Injuries

By GEORGE V. LEROY, M.D.

GEORGE VEACH LEROY attended the University of Pittsburgh and the University of Chicago. Trained in internal medicine, he taught and pursued his research work at Northwestern University. He served in the Pacific Theatre of World War II and the circumstances peculiar to military medicine directed his energies to a study of the effects of the atomic bomb. He returned to the University of Chicago where he continues his interest in the effects of atomic radiation as Professor of Medicine.

The syndromes which result from accidental exposure to harmful amounts of nuclear radiations are properly designated as *radiation injuries*. It is convenient to classify such injuries into the following categories:

1. *Whole body radiation injury* (also called radiation sickness, and the acute radiation syndrome) due to exposure to large amounts of penetrating gamma and/or neutron radiation at the time of the explosion of a nuclear weapon. Comparable injury may be sustained as a result of accidents with nuclear reactors or following sufficient exposure to residual radioactivity or the fallout from a nuclear weapon.

2. *Surface radiation injury* due principally to exposure to beta rays from contact, or near contact, with radioactive material, such as fission products and induced radioactivity. Comparable injury may be sustained as a result of accidental overexposure to ordinary x-rays or to the electron beams from particle accelerators.

3. *Internal radiation injury* resulting from the selective deposition, such as in bone or thyroid gland, of radioactive material inhaled or absorbed through the gastrointestinal tract or wounds. Comparable injury has resulted from the therapeutic administration

of radium salts and from the poorly supervised employment of radioactive material in industry.

The syndrome of whole body radiation injury should be clearly distinguished from *irradiation sickness* which is the term commonly applied to the symptom complex that occurs during therapeutic irradiation with x-rays or gamma rays. Whole body radiation injury has been observed and studied after four laboratory accidents in the United States, in the Japanese at Hiroshima and Nagasaki, and in American military personnel, Marshall islanders and Japanese fishermen exposed to radioactive debris which fell out after the field test of a nuclear device. In addition to these studies in human subjects, the syndrome has been produced experimentally in a number of species (monkeys, dogs, pigs, goats, burros, rabbits, rats, mice and bats) in attempts to define the pathogenesis and to develop rational, effective therapy.

The exposure which is responsible for whole body radiation injury may consist of high-energy gamma rays and neutrons emitted during the first few minutes after the atomic explosion or it may consist of exposure for several hours or days to gamma

the Japanese physicians that recovery was unlikely if the total leukocyte count was less than 500 per cu. mm. The approximate time-trend of the total leukocyte count in the three grades of injury are shown in Figure 6.

In the first few days after exposure the lymphocyte count has greater diagnostic value than the total leukocyte count. Lymphocytes start to decrease immediately after exposure. Pronounced lymphopenia appears within twenty-four hours. A total lymphocyte count less than 800 per cu. mm. forty-eight hours after exposure is presumptive evidence of severe radiation injury. A lymphocyte count in excess of 1500 per cu. mm. forty-eight hours after an atomic bombing indicates that radiation injury of the severe grade is unlikely.

With severe radiation injury, the neutrophils decrease less rapidly than the lymphocytes. With doses of radiation which are uniformly fatal to experimental animals, the total granulocyte counts are less than 1000 per cu. mm. within a week. With lesser doses of radiation, such low levels may be attained, but it takes much longer, perhaps ten to twenty days.

For the first three to four days following

Figure 6. Time-trends of total leukocyte counts observed in Japanese patients after exposure to atomic bombs. A, Approximate average values in patients with very severe radiation injury, twenty one of whom were studied in Hiroshima, and twelve in Nagasaki. B, Pooled data for 287 patients in Hiroshima with specific signs of severe radiation injury (i.e., epilation, purpura and oropharyngeal inflammation) who survived twenty-one days or longer. C, Pooled data

severe radiation injury, the thrombocyte count remains fairly stable. Beginning four to five days after exposure, the thrombocyte count drops rapidly, attaining values close to zero during the second week. Thrombocytes may remain at this low level for two to four weeks. In the less severe grades of radiation injury, the lowest values for the thrombocyte count occur in the fourth week.

In severe radiation injury, anemia develops slowly. It may be two to three weeks before it is evident. The lowest red cell counts are observed four to five weeks after exposure. A rapidly decreasing blood hemoglobin, red blood cell count or hematocrit reading is a serious sign and suggests rapid blood loss.

Reticulocytes decrease in number promptly and are almost absent for three to four weeks. Any subsequent increase in reticulocytes is a good prognostic sign.

A prominent clinical symptom of radiation injury is the hemorrhagic state which begins between the second and fourth week. The severity of this hemorrhagic state is closely correlated with the level of thrombopenia. It is characterized by an increased capillary fragility, prolonged bleeding time and prolonged clotting time.

The diagnosis of the syndrome of whole body radiation injury and the estimation of its severity depend on a proper evaluation of three factors: (1) The probability that nuclear radiation sufficient to cause injury reached the patient. This will depend on a knowledge of the patient's location at the time of the incident and an estimate of the geographical area at risk. If personnel dosimeters are available, the data obtained from them must be correlated not only with the foregoing, but also with the clinical symptoms. (2) The existence or the development of any or all of the typical symptoms of radiation injury. On the day of the incident it is proper to attach great significance to the presumptive diagnostic sign of vomiting. Particular attention should be directed to the tempo at which typical symptoms develop. Early appearance is indicative of greater severity of radiation injury. (3) The occurrence and the time-trend of leukopenia and lymphopenia are significant and should aid materially in the accurate evaluation of the severity of the injury. In conclusion, the diagnosis of radiation injury and the estimation of its severity constitute, essentially, a clinical problem and should be possible on the basis of a brief history, physical examination and a minimum of laboratory studies.

vescence takes place. Among the Japanese, the mortality rate for patients with severe radiation injury varied from 25 per cent to more than 50 per cent. It is likely that aggressive therapy is capable of salvaging many patients with this degree of injury, even though animal studies demonstrate that all cannot be saved. It is convenient to consider that severe radiation injury in man is equivalent to the type of injury which occurs in experimental animals given an LD₅₀ exposure.

Mild to moderately severe radiation injury occurs when the dose of radiation is in the range from 300 to 200 r to 75 to 50 r (or rep). In this form, vomiting may occur once or twice on the day of exposure. During the next two or three weeks there may be no symptoms at all or, at the most, moderate progressive malaise. During the third week or later, any of the characteristic symptoms of radiation injury (epilation, purpura, inflammation of mouth and throat) may appear, but it is distinctly unusual for all of them to be present or to be present in so severe a degree as occurs in the other forms. Constitutional symptoms and fever are not seen, except in association with obvious complications. The changes in the blood picture are less profound and occur somewhat later in the course of the disease. Among the Japanese during World War II, recovery was the rule for more than 90 per cent of the patients with this form of radiation injury. The deaths which occurred were the result of complications such as tuberculosis, chronic abscesses, bronchiectasis, refractory anemia and the like, and occurred as a rule later than the sixth week.

Whole body radiation injury of approximately this degree of severity occurred in some of the Marshall Islanders and the Japanese fishermen exposed to radioactive fallout following the detonation of a nuclear device at Bikini in 1954. In the case of the sixty-four residents of the island of Rongelap, the estimated dose was 175 r of gamma radiation. Constitutional symptoms and disability were minimal, even though skin lesions due to beta ray injury affected 90 per cent of this group. There were no fatalities among the Marshallese.

In general, patients with this form of radiation injury require no therapy except for well defined and obvious complications. Since, in any situation in which atomic weapons are used, the mild or moderately severe cases of radiation injury will far outnumber the severe ones, it is important that

these be diagnosed correctly so that they will not monopolize the medical facilities.

Diagnosis of Whole Body Radiation Injury. The diagnosis of whole body radiation injury should be entertained for all individuals who were within the area of destruction or fall-out of a nuclear weapon or who were in the vicinity of a reactor explosion. Under most circumstances, it is probable that military or civil defense authorities should be able to define a zone of potential injury beyond which there is small probability of the occurrence of significant radiation injury. In the case of accidents involving nuclear reactors, competent authorities should be able to assess the risk to individuals whose approximate position at the time of the incident is known. On the foregoing basis, it should be possible to separate survivors and casualties into two groups: those in whom exposure is possible, and those in whom it is unlikely.

Among the group who may have been exposed to injurious amounts of nuclear radiations, the occurrence of vomiting on the day of the incident is most significant. In fact, this symptom may be considered presumptive evidence of radiation injury. It is of interest that many Japanese physicians attributed the vomiting on the day of the bombing to psychologic causes, but subsequent analysis of the clinical data demonstrated that the relation between this symptom and exposure was indubitable. Vomiting on the day of the incident is an important factor in evaluation and in triage, since it occurs soon after exposure, and is not likely to be overlooked by the patient. Except for patients with the very severe forms of whole body radiation injury, no reliable clinical symptoms are evident until the second to third week when epilation, purpura, and oropharyngeal inflammation make their appearance. In general, the earlier the occurrence of these specific symptoms, the severer the radiation injury.

There is no single laboratory procedure which is, by itself, diagnostic for radiation injury. Exposure to harmful amounts of any sort of nuclear radiation produces leukopenia (lymphopenia and granulopenia), thrombocytopenia and anemia.

Leukopenia invariably follows whole body radiation injury. In the very severe type, the leukocyte count falls to less than 1000 per cu. mm. within the first week. With less severe degrees of radiation injury the lowest white cell counts are seen two to seven weeks after exposure. It was the opinion of

the Japanese physicians that recovery was unlikely if the total leukocyte count was less than 500 per cu. mm. The approximate time-trend of the total leukocyte count in the three grades of injury are shown in Figure 6.

In the first few days after exposure the lymphocyte count has greater diagnostic value than the total leukocyte count. Lymphocytes start to decrease immediately after exposure. Pronounced lymphopenia appears within twenty-four hours. A total lymphocyte count less than 800 per cu. mm. forty-eight hours after exposure is presumptive evidence of severe radiation injury. A lymphocyte count in excess of 1500 per cu. mm. forty-eight hours after an atomic bombing indicates that radiation injury of the severe grade is unlikely.

With severe radiation injury, the neutrophils decrease less rapidly than the lymphocytes. With doses of radiation which are uniformly fatal to experimental animals, the total granulocyte counts are less than 1000 per cu. mm. within a week. With lesser doses of radiation, such low levels may be attained, but it takes much longer, perhaps ten to twenty days.

THE HEAD

The Scalp and the Skull

By DANIEL RUGE, M.D.

DANIEL RUGE is a Nebraskan by birth and a graduate of North Central College and Northwestern University Medical School. He is a product of the residency training program in Neurological Surgery of his alma mater and is an Attending Neurological Surgeon at Chicago Wesley Memorial Hospital. Dr. Ruge has had fundamental training in the field of pharmacology and his investigative interests are concerned with the effect upon gastric secretion of various drugs introduced into the ventricular and subarachnoid systems.

The advancement of the machine age has subjected the scalp to an increasing incidence of trauma. The scalp serves as a covering of the skull and is a frequent site of infections and tumors of varied types. Scalp injuries and infections may result in osteomyelitis of the skull which may be further complicated by intracranial septic processes of the meninges and brain. Various cysts have a predilection for the scalp and hematomas of particular layers of the scalp are frequently encountered.

The scalp consists of five layers: the skin, subcutaneous tissue, the galeal aponeurosis with the epicranial muscle, subaponeurotic connective tissue and the pericranium, or external periosteum of the skull.

The skin of the scalp is very thick. Fibrous septa traverse the underlying subcutaneous tissue to join the skin to the galeal aponeurosis. There are numerous sebaceous glands in the true skin which may become cystic. The fibrous septa give the subcutaneous tissue a toughness and form an inelastic layer.

As a result, the numerous blood vessels in this layer do not contract when divided and this is the reason for the considerable hemorrhage which results from injuries to the scalp. Bleeding may be controlled by passing sutures through the subcutaneous layer and the galeal aponeurosis or by heavy pressure. Suture of the aponeurosis is essential in closure of scalp wounds and incisions, particularly when there is a defect in the underlying skull.

HEMATOMAS

Hematoma is a circular extravasation of blood in the subcutaneous tissue around the site of impact. At the center, the skin may become detached from the galeal aponeurosis and this will permit an effusion, around which is a zone of hemorrhagic infiltration in the subcutaneous tissue. The hematoma will present a soft compressible center surrounded by a hard peripheral subcutaneous layer. It may mimic a depressed fracture, but it should be recalled that in an adult a

Treatment of Whole Body Radiation Injury. At present (1959), there are available no specific agents of proved therapeutic value either for prophylaxis or for treatment following exposure to nuclear radiation. Treatment, therefore, must be symptomatic. In spite of the indifferent results of experimental therapy in animals, it is not proper to conclude that all efforts at treatment are a waste of time and material. Certain general principles which seem reasonable for the three grades of severity may be followed.

Very severe cases. Such patients will have received upward of 600 rep of whole body radiation. There is no satisfactory method for treating patients who have received the certainly fatal doses which produce this syndrome. Nausea and vomiting appear in one or two hours, followed by prostration within the first twenty-four hours. The experience of the Japanese indicated that these patients were very sensitive to physical activity, so that they should not be transported long distances. Palliation may be attempted by maintaining fluid balance and by adequate sedation. There does not appear to be any advantage in the use of antibiotics and blood transfusions merely on general principles.

Severe cases. In general, this includes patients in whom in the neighborhood of 400 r of whole body radiation was received. These persons need and profit most from good medical treatment. Although in the absence of trauma and burns they do not require active care in the first few days, strenuous activities should probably not be permitted.

Therapy should be directed at restoration of water and electrolyte balance and maintenance of general nutrition, control of infection and treatment for hemorrhage and anemia. The diet should be bland and low in residue. Intravenous fluids and parenteral alimentation should be given in the usual manner when indicated and when feasible, in an effort to maintain good nutritional status and to restore water and electrolyte balance in the presence of severe gastrointestinal symptoms. Infection can be controlled, at least in part, by the use of antibiotics. There is no reason to begin antibiotic therapy sooner than forty-eight hours after exposure unless required by wounds, burns or infectious disease. When there is

little doubt that a victim has been exposed to several hundred roentgens, it is wise, if adequate supplies are available, to start oral maintenance doses of an antibiotic by the third day.

Sulfonamides are probably not drugs of choice in radiation injury. However, if antibiotics are not available, they would undoubtedly prove lifesaving in certain instances.

The only effective treatment for hemorrhage and anemia is replacement therapy by blood transfusion. It would seem desirable, whenever possible, to maintain blood hemoglobin at a level of 10 gm. or more per 100 cc.

Mild to moderately severe cases. In the absence of complicating burns or wounds, patients with this grade of severity should not require treatment. It is desirable to limit their activity and maintain alert, expectant supervision of them. A firm policy with respect to this class of patient is imperative since they may well be the most numerous and the most demanding group of survivors. They should not be allowed to monopolize the medical services and they should not be given antibiotics or blood transfusions without very clear indications.

subcutaneous tissue. After the tumor has been present for some time, there may be irritation of the epidermis resulting in ulceration. Tumors of the scalp, as a rule, follow a benign course. Occasionally malignant degeneration takes place, in which event either basal or squamous cell carcinomas result.

Often these benign epithelial tumors are grouped together and in neglected cases they may become so numerous as to cover the entire scalp, giving the appearance of a turban. They may become lobulated, varying greatly in size. The large growths or those which become ulcerated require surgical excision. In all instances one must keep in mind that malignant degeneration can occur.

MALIGNANT NEOPLASMS OF THE SCALP

Malignant lesions of the skin are easily accessible for careful examination, early diagnosis and proper treatment. If proper therapy is to be administered, the patient should be seen when the lesions are small and the treatment given at a time when the disease can be eradicated.

It is helpful to differentiate between histologic types and the following classification is of clinical value: basal cell carcinoma, squamous cell carcinoma and adenocystic basal cell carcinoma.

Basal cell carcinomas are frequent. As a rule, there is a history of the lesion having been present for a period of months or years before it becomes active. They rarely result in regional or distant metastases, but it is believed by many that squamous cell changes may develop and these then gain access to lymphatic spread.

Next in frequency are squamous cell carcinomas. They grow rapidly and are subject to regional and distant metastases.

Adenocystic basal cell carcinomas clinically behave in a manner less active than the squamous cell but more active than the basal cell. There is considerable cellular differentiation.

While it is granted that malignant lesions of the scalp are rare, it must be remembered that they do occur. For this reason, patients with papillomas or other scalp tumefactions are often advised to have them removed lest chronic irritation, such as may result from combing or brushing the hair or pressure from a hat, may result in a malignant lesion.

Diseases involving the skull are for the most part similar to diseases involving other

osseous structures. Absorption of bone may result from general causes or from local pressure. Osteoclasts may be absent or they may dominate the process. Deposition of bone is on the whole dependent upon osteoblasts which line the deep layer of the periosteum, the endosteum and the haversian canals. Specific etiologic factors in aberration are often unknown. Different authorities may implicate infection, faulty metabolism or neoplasm in discussing the same disease.

CONGENITAL DISEASES AFFECTING THE SKULL

Craniolelaidodysostosis is a congenital condition in which there is a deficient formation of the clavicles and imperfect ossification of the cranium. Heredity is a large factor in etiology. It occurs equally in both sexes. Because there are great variations from case to case, it may be discovered at any age.

Röntgen ray examination reveals imperfect ossification of the membranous calvarium. The sutures often fail to close and the anterior fontanel may remain very large throughout life.

Craniosostenosis results from premature closure of one or more sutures, making the skull too small for its contents. There is frequently an increase in the depth and number of the convolutional impressions. The shape of the skull will vary according to which sutures are involved in the premature closure.

Megalocephaly (hydrocephalus) implies a head which is unusually large; the condition may be either congenital or acquired. The vault is unusually large as compared to the facial bones. All the bones are thin and the sutures may or may not be separated. If there is a marked intracranial pressure prior to closure of the sutures, there will certainly be a separation of the sutures.

Platybasia, a flattening of the base of the skull, is usually associated with a deformity of the foramen magnum. *Platybasia* may occur with basilar invagination, in which case the odontoid process projects above a line drawn from the hard palate to the posterior margin of the foramen magnum.

ACQUIRED AFFECTIONS OF THE SKULL OF UNKNOWN ORIGIN

Leontiasis ossea is hyperostosis of the skull; the etiology is obscure. It is considered by some to be neoplastic rather than dysplastic. The bones most often affected are the nasal, malar, maxilla, mandible and the

localized depressed fracture rarely occurs in the absence of an open wound. The infiltration is compressible and the hard edge of the swelling can be dispersed by pressure.

Subaponeurotic hematoma may result from rupture of subaponeurotic vessels. The hematoma may extend from the temporal crest and zygoma on one side to the temporal crest and zygoma on the other, and from the upper eyelids in front to the superior nuchal line behind. Rarely does infection occur. When it does, pus can spread in all directions and elevate the scalp. It may destroy the pericranium and cause necrosis of the calvarium. Thrombi may enter the dural sinuses via emissary veins. Incisions for evacuation of subaponeurotic abscesses are made parallel to the large vessels in the temporal area.

Subpericranial hematoma (cephalhematoma) is the most common form of hemorrhage in the young infant and the age incidence is believed to be due to the great vascularity of the pericranium in early childhood. In the fetal skull the pericranium, or external periosteum, lies in direct contact with the dura mater at the fontanelles. When the fontanelles are obliterated the pericranium becomes firmly attached to the skull at the suture lines.

A subpericranial effusion of blood limited by the suture lines may result following rupture of some of the blood vessels which run between the pericranium and the skull and is usually due to an injury during labor. Because of the deformity of the scalp, it may be mistaken for a fracture of the skull. Like the other hematomas of scalp, cephalhematoma is usually absorbed gradually and completely. The hematoma may ossify partially if absorption fails. In rare cases, only the periphery ossifies and the center becomes cystic. Such a bony prominence may persist for years, it is symptomless and as a rule requires no treatment.

SCALP WOUNDS

Every scalp wound may be a penetrating wound with injury to the brain. The most innocent-appearing wound requires proper attention for it may be the avenue to intracranial surgery should signs of intracranial hemorrhage occur subsequently. No scalp surgery should be undertaken without proper cleansing and adequate shaving of a wide area of the scalp around the wound. Control of hemorrhage is achieved by placing hemostats closely together in the subcutaneous galeal layers rather than by atten-

tion to the many anastomosing blood vessels.

Débridement of the wound edges should be accurate and conservative. Meticulous closure of a scalp wound involves suture layer by layer of the galea as well as the skin. Sutures may be removed after several days because the rich blood supply makes for early healing. Drainage is seldom necessary and when used should be discontinued after twenty-four hours. If a defect in the scalp exists, there is recourse to sliding grafts or pedicle flaps and again suture of both the galea and skin is essential. Care must be taken to have a good blood supply into the base of the flap. If this is certain one can expect good healing from a large variety of scalp flaps. Split-thickness skin is a feasible covering for denuded scalp.

EPITHELIAL CYSTS OF THE SCALP (WENS)

This type of cyst may be caused by occlusion of the orifice of the ducts of sweat glands, fat glands or hair follicles. The enlarging cyst flattens the secreting epithelium until it resembles squamous epithelium. The cystic substance consists of cast-off epithelium, fat and cholesterol crystals and may be solid, soft or liquid. The size is variable and frequently the cysts are multiple. They may undergo malignant degeneration, forming either squamous or basal cell carcinomas. They are attached to the true skin but are freely movable over the underlying connective tissue. Complete excision is, therefore, facilitated and should be done not only for cosmetic reasons but to avoid possible malignant degeneration.

Excision is performed after sterile preparation of the skin. A sufficiently wide area may be anesthetized with local anesthesia. An elliptical incision including the area of attachment of the cyst to the skin is usually made. The cyst wall is removed, preferably without rupture. The incision in the scalp should be sutured in layers. Care must be exercised to leave no part of the cyst wall to avoid recurrence.

CYLINDROMAS

This group of tumors of the skin occurs on the head and neck but more frequently involves the scalp, in which case they are referred to as turban tumors.

The tumor is well demarcated in the corium. It may be entirely separated from the epidermis by a connective tissue layer or it may be diffuse with strands extending out into the surrounding corium or the

pelvis. Lesions may appear later in the long bones. Spread is principally to the other bones. Metastasis to the internal organs is very rare.

The roentgen ray appearance is characteristic. The bone lesions are purely destructive but localized, so that they appear as punched-out round areas in a number of bones. Roentgen irradiation may cause prompt disappearance of the lesions, but rapid recurrence is common.

METASTATIC TUMORS

Secondary tumors of the skull are most likely to occur in carcinomas of the breast,

prostate, kidney (hypernephroma) and lung. The usual mode of infection is by the blood stream. The roentgen ray evidence shows that most of the tumors are purely osteolytic, the destruction not being associated with new bone formation. Tumors arising from the prostate, however, are osteoblastic as well as osteolytic and there have been instances of osteoblastic tumors arising from breast metastases.

The Eyes

By DERRICK T. VAIL, M.D.

DERRICK TILTON VAIL was born in Cincinnati and was educated at Yale and Harvard Universities. He chose to follow in the footsteps of his father, a distinguished ophthalmologist. He supplemented his training by work in India and Oxford. He was the Senior Consultant in Ophthalmology in the European Theatre of Operations in World War II and has held the Chair of Ophthalmology at the University of Cincinnati and Northwestern University.

From a general surgical viewpoint, the anatomy of the eye and its adnexa is relatively simple. However, a good working knowledge of it is essential to the proper understanding of surgical conditions pertaining to these structures.

Unless the general surgeon is equipped with special ophthalmic training and is familiar with the use of the small and delicate instruments, needles and suture material required in operations upon the eye, the ocular surgical conditions which he may encounter had better be referred to an ophthalmic colleague. There may be occasions, however, when the referral of a patient with an ophthalmic lesion cannot be done and the surgeon must therefore do the best he can with the tools he has.

The eyeball is well protected in front by the rim of the bony orbit, lids, orbicularis oculi, extraocular muscles and behind by a cushion of muscle tissue, fat and blood vessels. The area of greatest vulnerability is on

the temporal side and slightly below the horizontal. The wink reflex is exceedingly fast and thus forms a surprisingly good protection to the eyeball, because the rapidly closed lids receive the brunt of flying foreign bodies and burns. In addition, the lids are very rich in blood supply and thus resist infection, heal rapidly when lacerated or burned and, even when they appear gangrenous, often make an excellent recovery. This is important to know in order to avoid unnecessary loss of important tissue when débridement is considered.

The sinuous course and adequate length of the optic nerve, permitting wide rotations of the globe without stretching, also is on the side of the surgeon when the eyeball suffers a severe contusion. Indeed, patients were encountered during World War II in whom a blow to the lids and eyeball was strong enough to fracture the floor of the orbit by transmission of the force through these soft tissues, and yet the eyeball had

frontal and parietal bones. At first the changes are unilateral but may eventually involve the entire skull. Signs and symptoms depend upon which of the structures are compressed by the overgrowth.

Roentgen ray examination reveals irregular and mottled increased densities. The outer table is more affected than is the inner table.

Paget's disease (osteitis deformans) is characterized by slowly spreading changes in one or more bones. Decalcification combines with hyperostosis. Heredity may be a factor. The majority of patients seen are between fifty and seventy years of age. Males are affected more frequently than females. The femur, tibia, lower spine and skull are common sites.

In the skull there is a thickening of the outer table and irregular increased density. The sutures are obliterated. The changes are more likely to be generalized than in leontiasis and are less likely to involve the maxilla.

DISEASES AFFECTING THE SKULL RESULTING FROM ABNORMAL METABOLISM

Hand-Schüller-Christian disease, an uncommon condition, consists of craniohypophyseal localization of a lipoid granuloma of bone. There are multiple defects in the skull and other bones, exophthalmos and diabetes insipidus. There may or may not be other signs of pituitary dysfunction. It occurs typically in childhood, affects males more than females and there is no apparent hereditary influence.

Roentgen ray examination reveals a sharply outlined defect. As a rule there is no sclerosis in the periphery.

Letterer-Siwe disease (reticuloendotheliosis) is seen in infants and may be regarded as an acute form of Hand-Schüller-Christian disease. Lesions are found in the liver, spleen, glands, lungs, skin and skull. Radiographic appearance is similar to that in Hand-Schüller-Christian disease.

EOSINOPHILIC GRANULOMA

This is an inflammatory condition which is similar to lipoid granulomas but is rich in eosinophils and contains no lipoid elements. Males are affected five times more than females. The etiology is obscure. Lesions may be single or multiple. The bones most often affected are the ribs, skull, vertebrae, pelvis and humerus.

There are frequently no symptoms. Pain

is rarely severe. There may be a soft fluctuant swelling.

Roentgen examination reveals oval or circular, translucent and cyst-like punched-out and sharply defined areas.

The lesion is amenable to surgery. There is also value in radiotherapy.

OSTEOMYELITIS

Osteomyelitis is an inflammation of bone. In children the infection is usually hematogenous in origin. In adults the infection is usually from without and may result from spread from the sinuses or from a fracture. As the infection progresses the dead bone becomes separated from the living by the action of the osteoclasts and forms a sequestrum. When osteomyelitis appears in the skull or other membranous bones there is practically no reproduction as there may be in the long bones.

Treatment of osteomyelitis should include specific antibacterial medication with antibiotics or chemotherapeutic agents as well as surgical removal of sequestra and devitalized tissue. Open drainage of the soft tissue is essential to cure.

BENIGN TUMORS

Osteomas of the skull are compact outgrowths from the surface and are probably formed by the periosteal osteoblasts. It is proper to think of them as exostoses and not as true tumors. The most frequent site is in the frontoethmoidal or orbitoethmoidal region, but they may be found elsewhere. On roentgen examination there is a homogeneous density.

Osteochondromas are very similar to osteomas except that, as the name implies, they contain cartilaginous elements. They are apt to be pedunculated and may appear in the roentgenogram as masses of irregular density, but with clearly defined outlines. They are not associated with increased vascularity and produce no local bone reaction.

MALIGNANT TUMORS

Malignant tumors of the skull may be either primary or secondary. There are three principle types of primary bone tumor: osteogenic sarcoma, Ewing's tumor and multiple myeloma. Only the latter, which occurs in flat bones, is commonly seen in the skull. Multiple myelomas occur in patients over forty years of age. A striking feature is the multiplicity of the lesions. The flat bones containing red marrow are first involved, i.e., sternum, ribs, vertebrae, skull and

rotating the eyeball in or out as far as it will go, holding it in this new position with stay sutures, until a later time when plastic surgery has succeeded in making new eyelids.

Wounds of the orbit are generally due to perforating missiles or stabs. Often, in such cases, the eyeball is seriously injured, occasionally it may escape. Fragments of metal and plastic material, if sterile, are usually inert and can be left alone. If infection occurs, treatment with antibiotics, with or without drainage of the orbit, is usually efficient.

Often the trauma is accompanied by hemorrhage within the orbit, subperiosteal or within the orbital tissues, sometimes enough to cause an alarming ocular proptosis. In this event, a firm pressure bandage should be applied and maintained until bleeding has ceased. Care must be taken that the lids are closed as far as possible and the cornea protected by an antibiotic ophthalmic ointment, preferably 10 per cent sodium sulfathiazole. Once there is no further bleeding, the pressure bandage can be removed and a protective transparent plastic shield can be placed over the eye.

Operative interference to drain the blood is most disappointing and introduces the serious danger of infection, although in alarming cases, when the vision is threatened because of extravagant proptosis, lateral decompression of the orbit may be necessary. It is usually better to watch and wait, however. The orbital blood is slow to absorb, but generally the proptosis has subsided by the end of three or four weeks.

In the absence of a perforating wound, but when the skull is injured, hemorrhage into the orbit is a sign of fracture of its bony walls. The most serious danger to vision is a fracture through the optic foramen. The optic nerve can be hopelessly injured in this event, either through actual laceration of the nerve by sharp bone fragments or most commonly as the result of compression due to hemorrhage in the meningeal sheaths of the optic nerve. While it seems obvious that immediate decompression of the orbit foramen in this event ought to result in saving vision, very few of such maneuvers have been successful.

Early reduction of the fractured wall or walls of the orbit should be performed. In many of these injuries of the more severe type, the general condition of the patient may seem not to warrant early reduction, but, even so, unless there is cerebrospinal hemorrhage, repositioning should be

taken as soon as the period of shock is over, even in the presence of marked swelling and edema. Reduction of direct fractures can usually be accomplished by closed methods of manipulation soon after the accident, although the approach may tax the ingenuity and skill of the surgeon. It must be borne in mind that orbital fractures heal very quickly and, unless reduced early, serious deformity results. Simple reduction is hopeless to try after three weeks.

Ocular proptosis, or exophthalmos, can be due to a great many things. It may be bilateral or unilateral, apparent or true, and an accurate diagnosis must be made in order to give proper treatment. Most often the diagnosis is difficult and requires most careful studies, repeated observations and consultation with colleagues in many fields of medicine.

Apparent proptosis may be the result of orbital fat, a familial feature, or facial asymmetry. In the presence of swelling, edema of the lid or inflammation, proptosis may be simulated. Purely ocular causes, such as iritis or glaucoma, and inflammatory lid conditions may yield an apparent proptosis. There are also rare cases of voluntary or semivoluntary forms of ocular proptosis.

In some cases in which there is an enophthalmos or retraction of the globe within the orbit, as in Horner's syndrome, or fracture of the floor of the orbit, for example, the opposite eye by comparison may appear to be proptosed. Likewise, when there is a slight ptosis of the upper lid, the other eye may appear to be exophthalmic. Nor is it unusual to see a patient who shows a retraction of the upper lid without exophthalmos, which may be unilateral, and is due to past or present thyrotoxicosis.

The determination of true proptosis is made by measurement of the degree of exophthalmos either with the Hertel exophthalmometer or by means of a transparent Lucite millimeter ruler. These instruments permit one to make a measurement of sufficient clinical accuracy to record the variations of degree of proptosis from time to time. A difference of 3 mm. between the eyes is of significance.

Inspecting the two eyes in a good light and noticing whether the eyeball is displaced forward vertically or laterally is of importance, because the direction of the proptosis is often helpful in deciding its cause. In order to discover slight degrees, it is sometimes necessary to elevate both of the lids simultaneously and have the patient

suffered surprisingly little permanent damage, and sight was little affected, although the intraocular coats, particularly the choroid, might have been ruptured.

EMERGENCY SURGICAL CONDITIONS

When a person is seriously injured, unconscious and in shock, it is rare that the surgeon pays any attention to the condition of the eyes. If the eye is injured, this can have most serious consequences to sight. An inspection of the eyes must always be made as a routine part of the study of such a patient and, if the eyes are found to be injured, they should be treated as soon as the general condition of the patient will permit. Since much of the surgical repair can be done with the patient under local anesthesia, there is no need to postpone such repair unduly.

The inspection of an eye should be made in a good light, preferably a beam of light focused onto the eyeball with a condensing lens. A good flashlight is often most adequate. If the lids are swollen and in spasm, it may be necessary to open them with lid hooks or small retractors gently inserted beneath them. One should observe the cornea and corneal reflex, the anterior chamber, the pupil and, upon gently rotating the eye, the bulbar conjunctiva and sclera and the insertions of the four rectus muscles. The condition of the red reflex, as seen with the ophthalmoscope, should be ascertained. Gentle finger palpation of the eyeball in the absence of a perforating wound of the globe, will give a rough idea as to the state of the ocular tension—whether the eyeball is soft, indicative of a rupture or perforation of the sclera, or hard, indicative of intraocular hemorrhage.

Lacerations of the lids are common. Although they are usually the results of injury by a sharp object, they can also be caused by contusions and concussions. The lids should be cleansed with soap and water and the extent of the laceration and the structures involved ascertained. Infiltration of the affected area with procaine solution gives efficient anesthesia. Primary closure of the laceration, preferably with 5-0 or 6-0 silk sutures spaced closely together, can then be done without difficulty. If the laceration is deep and extends to the orbital periosteum or through the tarsal plate, repair of this part of the wound with 5-0 or 6-0 gut sutures should be carefully performed before the skin is closed. The tissues should be

replaced as accurately as possible in their original position.

Lacerations of the lid margin present slightly more difficulty. In order to prevent an eversion of the lid, the margins must be exactly approximated. The key suture here is through the intermarginal areas, one to the other, tightly tied so that a slight elevation of the joined edges occurs. This always flattens out later. The remainder of the laceration is then sutured, usually quite easily.

A laceration through the lids involving the upper, or particularly the lower canaliculus of the lacrimal apparatus (nasal side of the lids) is one of the most difficult and at the same time the most important to handle properly at the first instance. It is necessary to identify the two cut ends of the canaliculus exactly. A sterile probe of small wire, no 1 catgut, preferably chromicized, or heavy linen thread is inserted into the punctum, then through the canaliculus, joining both ends, and either well into the nasolacrimal duct or at least into the tear sac, and held in place by whip sutures. The laceration is then properly sutured. The guide suture or wire is left in place for at least four days or longer if it is not causing a tissue reaction. If suturing is not done at once, later, when scar tissue forms, it is usually impossible to identify the ends of the cut canaliculus and to have a patent functioning tubule.

Ten per cent sodium sulfacetamide ophthalmic ointment, or other antibiotic ophthalmic ointment, is then placed on the lids and a firm eye pad, pressure bandage combination is applied. There is generally no need to inspect the wound for two or three days. The sutures should be removed in four to five days.

Burns of the lids may either be thermal or chemical in origin and present the same problems as do burns of the skin elsewhere. Gentle but thorough cleansing with soap and water and the occasional application of an ophthalmic antibiotic ointment may be all that is necessary in mild injury. In severe third degree burns, however, it is essential that the eyeball be protected by suturing the lid margin together or, if there is too extensive loss of tissue to insure this, by covering the cornea with a conjunctival flap or, in desperate cases, by bringing a sliding skin flap over the eyes from above or below, or even by cutting all four of the rectus muscle tendons at their insertions and

removal of a tumor which lies in the middle part of the orbit is best accomplished by the Kronlein approach.

Severe progressive (malignant) exophthalmos may require unroofing of the orbit in order to save the eye and sight, by permitting herniation of the enormously thickened muscle cone and the relief of the eyeball from pressure. The operation is futile when the muscles are completely hyalinized and no longer are elastic.

Tarsorrhaphy, or the sewing of the lateral third or half of the eyelids together, is a useful operation designed to protect the eyeball from dangerous exposure in moderate degrees of exophthalmos.

Wounds of the globe may be penetrating or perforating, single or multiple, or due to concussion. Perforating wounds of the cornea may extend into the sclera or may remain localized in the cornea. When such a wound occurs, there is immediate loss of aqueous humor and the iris pushes forward to plug the wound or prolapse through it. If the injury is severe enough, loss of the lens and vitreous humor occurs and thus total loss of the eye may result.

It is for these reasons that a most careful examination of a corneal injury should be made. Not only should the eye be handled most gently, but the patient should not be ambulatory until after the wound has been repaired.

If the examination of the eye shows that iris or ciliary body prolapse has occurred, the prolapsed tissue must be excised and the wound closed with direct appositional sutures. Care must be taken not to place the sutures too deeply in the cornea, because of the danger of fistulization of the wound or growth of epithelium into the anterior chamber. This procedure requires great skill and delicacy, for undue pressure upon the eyeball may express the lens and vitreous humor.

It is sometimes easier to close the wound by covering it with a conjunctival flap. In this procedure, the conjunctiva is separated from the limbus and sclera in the area adjacent to the wound. Following excision of prolapsed uveal tissue, the loose conjunctiva is then brought over the wound and sutured in the limbic zone on each side like an apron.

Or, peritomy of the corneoscleral margin can be done and the entire bulbar conjunctiva separated from the sclera by blunt dissection. The loose conjunctiva is then

brought over the cornea and closed with a purse-string suture.

An x-ray photograph must be taken of every eye which has had a perforating or penetrating injury, for this constitutes a medicolegal responsibility. It is surprising how often the x-ray photograph reveals the presence of an opaque intraocular or intra-orbital foreign body that is usually metallic and, fortunately, generally magnetic.

However, a simple anteroposterior or frontal x-ray photograph is not enough, for the removal of a magnetic foreign body, with minimum additional trauma to the eye, is one of the most difficult ophthalmic operations to perform successfully.

For proper removal of a magnetic intraocular foreign body, it is entirely necessary to know its exact location within the eye and its exact size. This requires most expert skill in localization with x-ray photographs and accurate charting of the result. The Sweet method of localization is the one most frequently used and has stood the test of time. Many roentgenologists are quite skilled in its technique and are able to localize the foreign body within a fraction of a millimeter. Others, unfortunately, are less skilled and have reported the foreign body as outside the eyeball when it is within it, or vice versa, errors which can be most dangerous, or at least embarrassing.

A new and valuable adjunct to the exact localization is the use of the Berman localizer, an instrument the principle of which on a minute scale is that used in the detection of land mines.

Having determined the exact size and position of the foreign body, the surgeon makes an incision into the sclera, choroid and retina in the area closest to the foreign body. The incision must be large enough to permit withdrawal of the object with the sterile tip of a strong hand magnet. The wound area then is stippled with diathermic ignipuncture to prevent secondary retinal separation, and the scleral wound is closed with fine silk sutures, or other sutures, as required.

One of the most valuable lessons learned in World War II was the fact that there is no great urgency in removing an intraocular foreign body. It is far better to wait until accurate x-ray localization can be obtained and the services of an expert ophthalmic surgeon are available than to cut into the eyeball and blindly apply the magnet.

The removal of a nonmagnetic foreign

gaze directly forward. It is often better to stand behind the patient, who is seated on a low chair or stool, and look down across the plane of the orbits from above. It is also wise to sight along the plane of each orbit from the lateral or profile view.

Ocular motility is then tested and limitation of movement in any direction of gaze is noted. An analysis of the limitation of ocular motion is of value in the diagnosis of the site of the lesion and frequently of its cause.

Palpation and stethoscopic examination of the orbit give useful information at times. Palpating the orbital contents may reveal the presence of a tumor. In addition, one can obtain a rough estimate of the degree of the orbital pressure. It is always necessary to have x-ray photographs made. These should include plates of the skull as a whole, the orbits, sinuses and the optic foramen of both sides. A nose and throat examination is frequently advisable. Blood studies may be indicated and other laboratory tests, such as a determination of the basal metabolic rate or iodine uptake studies, are often advisable in order to arrive at the proper diagnosis.

True proptosis may be classified for the purpose of differential diagnosis in the following manner:

I. Monocular

A. Rapid proptosis with edema of the lids

1. Ocular (glaucoma, iridocyclitis, panophthalmitis, tenonitis)
2. Orbital (cellulitis, cavernous sinus thrombosis, hemorrhage)

B. Gradual proptosis without edema

1. Congenital malformation of the orbit (encephalocele, meningocele)
2. Ocular enlargement (high myopia, buphthalmos, anterior megalophthalmos, intraocular neoplasm perforating posteriorly)

C. Unilateral proptosis with central displacement

1. Thyrototoxic or progressive exophthalmos
2. Vascular causes (arteriovenous aneurysms or pulsating exophthalmos)
3. Tumors of the optic nerve or those arising in the optic foramen
4. Cysts of the orbit
 - a. Congenital (meningocele, se-

rous cysts seen in congenital microphthalmos, dermoid cysts)

- b. Acquired (cysts which are developed as the result of exudation and the inclusion of epithelial tissue as a result of trauma or around neoplasms, parasitic cysts [hydatid or cysticercus])

5. Neoplasms of the orbit

- a. benign as in pleuiform neuroma
- b. Malignant (mixed tumor of the lacrimal gland, primary sarcomas, metastatic neoplasms, chloroma, pseudo-tumor, malignant lymphoma)

6. Foreign bodies

D. Unilateral proptosis with lateral displacement

1. Mucocele from the sinuses, neoplasm from the sinuses, bony exostosis from the orbital walls (osteoma, meningioma), the result of nasal surgery (radical frontal sinus surgery), orbital osteoperiostitis, meningocele, emphysema of the orbit

II. Binocular

1. Congenital or as a familial trait
2. Tower skull
3. Graves' disease, including progressive (malignant) exophthalmos
4. Neoplasms arising in the ethmoid or sphenoid sinuses extending into both orbits
5. Double-sided sinusitis (pansinusitis)
6. Neurofibroma
7. Myasthenia gravis
8. Cavernous sinus thrombosis
9. Mikulicz's disease
10. Sarcoidosis
11. Cranio-orbito-facial malformations

Thus, we see that the sign of exophthalmos is a complex matter which demands careful investigation.

The removal of an orbital tumor, especially when it is decided that it lies in the posterior third of the orbit, is best accomplished through frontal craniotomy and unroofing of the orbit. Many of these tumors are found to arise within the skull and invade the orbit by direct extension. The

found the first eye muscle and pulled it easily forth with my Maudsheim-made instruments. Soon all the eye muscles were cut. The most dramatic moment arrived when I felt for the optic nerve, the only sound being the clicking from the film camera in the background. Successfully severing the nerve, I then extracted the eye globe and tied the eye muscles together, closing the wound with conjunctival membrane. The operation was successfully over after an exciting two hours and forty minutes."

In enucleation of the globe, first a lid speculum is inserted, then the conjunctiva is incised at its insertion at the cornea, the incision is enlarged all around the cornea (peritomy) and, with blunt dissection, the conjunctiva is undermined and separated from the sclera as widely as possible. This will expose the rectus muscles. A muscle hook is then inserted beneath the tendon, beginning with the superior rectus muscle, and going on to the medial and inferior rectus muscle, cutting as closely as possible to the globe and thus avoiding some bleeding. The last muscle to be severed is the lateral rectus. Enough of a stump of this muscle is left attached to the eyeball so that it can be strongly grasped with tooth forceps or hemostat. The eye is rotated medially. A half-curved, blunt-pointed scissors is inserted along the temporal side of the eyeball, between it and the separated conjunctiva, and when the scissors is behind the globe search is made for the optic nerve, which is a firm, cordlike structure. The nerve is then placed between the blades of the scissors and cut. At the same time the eyeball is pulled and tags of restraining tissue (superior and inferior oblique muscle tendons) are cut off. There will be a smart hemorrhage when the nerve is cut and the eye removed. This is controlled by a cone-shaped tampon of cotton placed beneath the conjunctiva into the socket and held with firm finger pressure directed toward the apex of the orbit. Bleeding should stop well within ten minutes. When it stops the tampon is removed and the conjunctiva is sutured together with three well-placed 3-0 to 4-0 interrupted silk sutures. Sulfacetimide ophthalmic ointment is placed in the eye and the lids are closed, eye pads and a firm elastic or adhesive plaster bandage are applied. The sutures can be removed in five days and an artificial eye inserted in ten days.

In the event of panophthalmitis, the eye

should be eviscerated. The cornea is completely excised and the contents of the eye are scooped out with a blunt curet. Care should be taken to remove all of the pigment tissue. The inner walls of the scleral cavity must be white everywhere. There will be little or no bleeding when the cavity is entirely clean. Sulfacetimide ophthalmic ointment is inserted and the lids are closed and covered with an eye pad and a firm bandage.

Thermal and actinic burns of the eyeball are relatively rare. Most commonly they occur as the result of are welding or long exposure to harmful ultraviolet light. In these conditions the eyes are usually quite painful. The application of cold compresses and sulfacetimide ophthalmic ointment and the occasional instillation of a drop of 1:1000 solution of Adrenalin chloride usually relieve the patient and the eye heals readily in twenty-four hours.

Severe burns of the eyeball affecting the bulbar tarsal conjunctiva and cornea are most difficult to treat because the cornea generally perforates with loss of the intraocular contents. However, ice compresses of saline solution, atropine and sulfacetimide ophthalmic ointment and frequent separation of the lids from the bulbar conjunctiva to prevent adhesions are employed. In deep bulbar conjunctival burns, immediate graft with a suitable piece of buccal mucous membrane should be made.

Chemical burns are not rare and each employee of a chemical plant or workers in chemical laboratories should receive instruction in first-aid treatment of this condition. The opened eye is irrigated copiously with tap water, preferably using a fountain syringe with a rubber tip, for a full five minutes. The eye is then carefully inspected, a drop of 0.5 per cent solution of Pontocaine is instilled, followed by a drop of 2 per cent fluorescein solution to stain the burned or abraded cornea in order to reveal the extent of the damage. All foreign bodies are removed with a toothpick swab and the eye is gently irrigated for fifteen minutes with warm normal saline solution. The eye is again stained with fluorescein and irrigated. If the greenish stain is retained by the cornea, it indicates a definite chemical burn and the patient should be referred to an ophthalmologist for definitive care.

In the past, attempts have been made to neutralize the responsible chemical by suitable chemical agents, but experience has shown that simple but thorough flushing of

body is exceedingly difficult, often impossible. If the foreign body is near to the retina and choroid it sometimes can be grasped through a scleral incision with suitable forceps and withdrawn. Such an event is most fortunate.

Of all the innumerable kinds of nonmagnetic foreign bodies reported, those composed of copper or its alloys are the most dangerous to leave within the eye, for the metal undergoes oxidation and produces copper oxide, a substance that is highly toxic to the intraocular contents. Stone, glass, wood and plastic material can often be well tolerated sometimes for a long time provided no infection occurred in the beginning.

Injuries to the lens are common and generally produce complete opacification (cataract) of it in a short time, for when the capsule of the lens is opened, aqueous humor enters into the lens fibers and leads to cloudy swelling. The cataractous lens is removed by several methods, depending on the age of the patient and the condition of the eye.

When the lens is removed (aphakia), there is no focusing power remaining in the eye and the patient must wear a substitute lens in a spectacle frame. If a contact lens is tolerated a host of difficulties is avoided. Usually, however, when the uninjured eye is sound and has good vision, correction of the refractive error in the aphakic eye causes confusion between the two and binocular single vision is impossible to attain for a number of optical reasons.

However, an aphakic eye, without correction, if otherwise sound, still has most useful peripheral vision and in addition is a reserve eye in case anything should happen to its fellow.

Injuries to the choroid, a highly vascularized tissue, generally consist of ruptures of this ocular coat. Severe intraocular hemorrhages either into the retina or breaking through into the vitreous always occur in this event. The location of the rupture, which is generally in the posterior pole of the eye, will determine whether or not useful vision is retained after the hemorrhages are absorbed.

If the macula of the retina, the fixation point of vision, is damaged, the resultant central scotoma in the field of vision is permanent. If the periphery of the retina is affected, central vision may be retained and may even be normal.

Injuries to the retina may or may not

result in a tear or tears of this membrane. If the retina is torn, separation or detachment of it almost always ensues. In this event, surgery is necessary and consists of first localizing the tear as exactly as possible with the ophthalmoscope and then treating this area with perforating diathermic ignipunctures, in order to produce points of adhesive chorioretinitis, thus sealing the retina back in its place. Obviously, the exact localization of the tear in the retina requires utmost skill in the use of the ophthalmoscope, and the technique of diathermy coagulation of the retina is one that demands much experience and special training in its use. About 70 per cent of the patients having retinal detachment, both traumatic and idiopathic in origin, are successfully treated by this method in the hands of experts.

If a perforating injury of the eyeball occurs, particularly when it involves the iris or ciliary body, the risk of subsequent sympathetic ophthalmia is ever present and is always to be considered. This is a most difficult problem to solve. Fortunately, sympathetic ophthalmia rarely occurs before the tenth day following injury, so that there is a certain leeway in deciding whether or not an injured eye should be removed. Also, it is consoling to know that sympathetic ophthalmia is quite rare, for example, very few of these cases occurred during World War II. Thus, a conservative approach is always best unless it is obvious that the eyeball is hopelessly injured and that there is no prospect of useful vision. Therefore, if expert ophthalmic care is available, the general surgeon is never justified in removing an injured eye but leaves it to his colleague to assume the grave responsibility of decision.

If, however, such is not the case, and if the injured eye remains inflamed and soft, with vision markedly reduced for more than a week, it may be necessary for the general surgeon to remove the eye. This emergency happened to Dr. Ove Wilson, the only surgeon with the joint British-Scandinavian Antarctic Expedition in Maudheim, Antarctica, on July 21, 1953. He was faced with the necessity of removing the injured right eye of a fellow member of the group, an operation that he had neither seen before nor ever performed. In writing to the *London Times* about this experience later, he said, "Waiting for the operating moment I recapitulated all details of the operation in my mind, wondering whether I should be able to find all the different eye muscles and the right place to cut the optic nerve. . . . I

normal mucous membrane cannot meet the burden of added humidification and drying increases the viscosity of the mucous blanket. Irritants and bacteria are not carried away and, under these circumstances, the mucous blanket becomes a medium actually encouraging bacterial growth. Prolonged congestion and irritation caused by the infection produce hyperplasia and permanent respiratory obstruction results. Numerous local and general symptoms are produced and the opportunity exists for extension of the infection to other organs.

The original obstruction may be produced by either functional or structural changes in the nasal cavities. Allergy, chemical irritants, dust, fumes, swimming and diving, menstruation, endocrine imbalance, dietary deficiencies and any condition which produces circulatory changes may be the etiologic factor. The structural changes are of more surgical significance. These include deviations of the nasal septum, septal spurs, hyperplasia of the nasal turbinates, synechiae, bone cysts, exostoses, nasal polyps or other nasal tumors, choanal atresia, hypertrophied or infected adenoids, rhinoliths and other foreign bodies. Any or all of these conditions can usually be corrected by surgery.

Perhaps the most frequently found cause of varying degrees of nasal obstruction is a deviation, or deflection, of the *nasal septum*, the result of an asymmetrical malformation of the cartilaginous or osseous, or both, portions of this structure. In some instances, such a deformity is the result of trauma to the nose and septum but most often is the end result of overgrowth of the septal components. Since insufficient space is available to accommodate the overgrowth, buckling, bulging, twisting and overriding of portions of the septum occur. At times a high, arched palate is responsible for the lack of space available for septal growth, but such a palate deformity is not invariably accompanied by a septal deflection. This adds credence to the view that overgrowth, or redundancy, of the septal parts is responsible for most septal deformities, with trauma second in importance.

There is wide variation in the form and degree of deviation produced, but the types of deflections seen tend to fall into certain patterns. The normal septum is essentially straight from top to bottom and from front to back and the variations from this normal pattern can be classed as convex deviation, sigmoid deviation and septal ridge. The convex deviation produces a unilateral bulge, more or less continuous from top to bottom,

which narrows one nasal cavity and produces overpatency of the opposite side. The sigmoid deviation is an S-shaped deformity that blocks one side above and the other side below. An S-shaped buckling can also occur that blocks one side anteriorly and the opposite side posteriorly. The septal ridge is a prominence running horizontally from front to back. A more severe form of buckling occurs in which both bone and cartilage are crumpled and irregular ridges and sulci on both sides of the septum are produced. A very common type of deformity is one in which the lower end of the cartilage is dislocated from its groove in the nasal spine of the maxilla and presents in the nostril. All of these deformities are often associated with spurs, crests and ridges of various shapes and external deformity is frequently produced.

The symptoms produced by deflection of the nasal septum depend upon the degree of distortion and the area in which obstruction is produced. This may vary from mild interference with nasal breathing to obstruction severe enough to occlude sinus drainage. Pressure of the deflection, spur or ridge on nerves may produce neuralgia referred to areas about the head, face, eye and ear. Overventilation of the unobstructed side may produce drying and infection, resulting in disease and symptoms in the overpatent side.

There are few conditions which can be confused with a deflected nasal septum if the diagnosis is made by direct examination. Symptoms of nasal obstruction give no clue as to the condition responsible.

If the obstruction produced by a deflected septum requires treatment, the treatment is of necessity surgical. The results of surgical correction are uniformly good when the procedure is done by an adequately trained surgeon. In most cases, a satisfactory airway can be restored. The effect of the restored airway on the secondary complications of the pre-existing nasal obstruction depends on the length of duration, severity, extent of changes produced, the physical condition of the patient and the persistence of after-treatment of the secondary condition.

The operation for correction of a septal deviation is known as a submucous resection and is accomplished by incising the septal mucosa and perichondrium to the cartilage just posterior to the anterior nares, usually on the convex side of the deflection. The perichondrium and periosteum are carefully elevated from the cartilage and bone of the septum, care being taken to avoid tearing

the conjunctival flap with tap water for five minutes is much more simple and efficient. Occasionally, the neutralizing solution is quite irritating, even harmful. Besides, the neutralizing solution is rarely at hand for immediate use.

NONEMERGENCY CONDITIONS

Surgical conditions which are nontraumatic in origin, such as the removal of cat-

aract, correction of ocular muscle anomalies, operations for glaucoma and detachment of the retina, keratoplasties and surgery of the lacrimal apparatus, are properly the domain of the ophthalmic surgeon. Plastic surgery of the lids and orbit is a highly specialized procedure and requires special training and experience in order to obtain the best results.

The Nose, Nasal Accessory Sinuses and the Pharynx

By FLETCHER AUSTIN, M.D.

FLETCHER AUSTIN is the son of a physician who practiced in Illinois and later moved to Ohio. After graduating from Ohio State University, Doctor Austin attended Northwestern University Medical School and there earned a Master of Science degree in Anatomy. He received his training in otolaryngology in Iowa and New York. He believes that the problems of the ears, nose, larynx and pharynx have not all been solved by the advent of chemotherapy and the antibiotics and that one should have a broad base in surgical training before extending the scope of any particular surgical specialty. Doctor Austin is an Associate in Otolaryngology at Northwestern University.

THE NOSE

The rhinologist is consulted primarily because of impaired function, disease or cosmetic appearance of the nose. The nose is the starting point of many infections which may subsequently involve the sinuses, pharynx, ear, eye, gastrointestinal tract, bronchopulmonary system, the kidneys and the blood and lymph circulation. In addition, it is affected by congenital and acquired malformations, specific infections and neoplastic involvement. There are some common intranasal conditions that impair the function of the nose, in which surgical treatment may be reasonably expected to aid in restoring the normal physiology.

The basic function of the nose is respiration and olfaction is second in importance. The nasal cavity also acts as a resonating chamber for the voice and is the origin and recipient of numerous reflex arcs.

The secretions of the nose possess a bacteriostatic property. The vestibule of the

nose is lined by skin containing hairs, or vibrissae, which defend the nasal cavities against the intrusion of foreign material. The nasal structures are richly vascular and the inferior turbinates have a cavernous structure that is essentially erectile tissue. The mucous membrane of the nasal cavity is ciliated and the action of the cilia constantly moves a thin blanket of mucus toward the nasopharynx. These are the mechanisms which clean, warm and moisten the inspired air, preparing it for reception by the lower respiratory tract and the lungs. In order to properly accomplish this, the entire nasal mucosa must function normally. If, for any reason, the ventilation and drainage of any part of the mucosa are interfered with, symptoms will develop. The normal movement of the blanket of mucus is impaired, dust and bacteria are not removed and the membrane becomes infected. The resulting congestion causes increased obstruction and a vicious cycle is established. The remaining

small superficial vessel. Digital trauma to the area is the most common inciting cause. The bleeding vessel in many instances is so close to the anterior nares that compressing the nostrils between the thumb and index finger may stop the hemorrhage. A small pack, moistened with an ephedrine, Adrenalin or cocaine solution and firmly, but not forcibly, placed against the area may be necessary if the bleeding is brisk. Once the bleeding point is located, the offending vessel may be destroyed by the application of chemical or high-frequency cautery.

Severe, persistent hemorrhage and inability to find the bleeding vessel may require firm packing of the entire nasal cavity and the introduction of a postnasal pack. It is often helpful to pack the nose in segments, which aids in determining from what area the bleeding is arising.

If nasal hemorrhage cannot be controlled or recurs at frequent intervals, a careful study must be made to determine if a blood dyscrasia, neoplasm or some condition other than simple rupture of a vessel may be responsible. Ligation of the external carotid artery is sometimes necessary to control the hemorrhage and save the life of the patient.

Formation of a *furuncle* is a common, painful and potentially dangerous condition which occurs about the nose, forehead, upper lip and in the nasal vestibule. Venous drainage from these areas forms a fairly direct route through the ophthalmic vein to the cavernous sinus and fatality from cavernous sinus thrombosis has followed improper treatment of a seemingly simple, circumscribed infection in one of these locations. Such an infection should be treated by warm fomentations and the patient confined to bed. These furuncles should not be incised but should be allowed to resolve or drain spontaneously. Picking and squeezing of the lesion should never be permitted. Early use of antibiotics is indicated if the infection is at all severe.

Fracture of the nasal bones is due to direct violence and the displacement which occurs usually depends upon the direction of the blow producing the fracture. The bones may be pushed directly backward, crushing or buckling the septum beneath them, or the displacement may be in a lateral direction. Such fractures may be compound or comminuted. The fracture frequently occurs at the junction of the nasal bone with the nasal process of the superior maxilla, because of the relative thinness of the bone at this point. The nasal process of the maxilla is frequently included in the fracture. Frac-

ture at the glabella does not often occur because of the thickness and density of the bone in this region. Fracture of the nasal bones may occur with no displacement of the fragments and in this case no manipulation is necessary, although the nose should be protected from further injury by splinting.

If displacement occurs, reduction should be done before swelling obscures the deformity. The depressed or displaced bones may be brought into proper alignment by introducing a closed forceps or a flat, rigid elevator into the nasal cavity and lifting the bones and molding them into place by counterpressure applied by the fingers externally. If they tend to sag back into the nasal cavity, petrolatum gauze packing high in the nose will support them in place until the healing processes will maintain the reduction.

The nasal septum is often injured by the trauma producing the fracture of the nasal bones or the septum alone sustains the injury. If the septum is dislocated from its attachments, it may be grasped between forceps blades protected by rubber sheathing and lifted or rotated into place. The septum is sometimes fragmented or so distorted that replacement is difficult. In such cases, a submucous resection done at the time, to remove the bone and cartilage so involved, will hasten healing and prevent later obstructive deformities.

At times the nasal bones are so severely fractured and displaced that it is necessary to hold them in place by transfixing wires or sutures, or by devising an apparatus which will exert mild sustained traction. If reduction of the fracture has been delayed two weeks or more, it may be necessary to break up the existing bony union by the use of chisels to achieve restoration of the bones to their normal position. This constitutes an open reduction and is usually accomplished by employing the techniques used in rhinoplasty.

An external splint fashioned from dental compound, or of metal, shaped to fit the nose and extending from the forehead well down past the nasal bones is held in place by adhesive strapping to protect the reduction until union of the fragments is firm. Loose intranasal packing with petrolatum gauze is also usually required.

THE NASAL ACCESSORY SINUSES

Acute and chronic infection of the paranasal sinuses is almost always bacterial in origin, but the development of inflammatory

or perforating the membrane. This elevation is extended to include the total area of deformity. The cartilage is then cut through, at the point of the initial mucous membrane incision, to the perichondrium of the opposite side and that membrane is elevated in a like manner and with the same care. The deformed cartilage and bone are removed in segments, bleeding is controlled, the space between the flaps formerly occupied by the septum is cleansed of fragments of bone and cartilage and the flaps are approximated and held together by firm packing of the nasal cavities for twenty-four hours.

A laceration or perforation of one or both of the membrane flaps during the operation is of little consequence unless the tears or perforation appose when the flaps are closed. In this instance, a permanent perforation of the membranous septum is almost sure to result. Replacing a piece of straight cartilage between the two lacerations may prevent this complication.

Trauma to the nose may produce a *hematoma* beneath the perichondrium or periosteum of the intact septum, or a hematoma may occur between the apposing membranes following a submucous resection. It is more commonly the result of trauma and, although it occurs more often in children than in adults, it is seen in persons of all ages owing to the increasing frequency of head injuries. When it occurs, it usually produces obstruction to both nasal airways. Palpation will make the diagnosis if it is not recognized by sight; the softness and fluctuation differentiate this lesion from a solid obstructing mass. The treatment is free incision at the base of the hematoma with careful removal of the blood, clots and any bone or cartilage fragments. Gentle suction may be used, but irrigation of the space may cause further elevation of the mucosa and introduce and spread infection. The incision should be kept open by a drain until any danger of recurrence is past. Antibiotic or sulfonamide therapy lessens the danger of supervening infection.

Failure to drain a hematoma may result in marked thickening of the septum and permanent nasal obstruction. The hematoma may become infected and a septal abscess may develop.

In instances in which a *septal abscess* develops, there is usually a history of trauma followed by nasal obstruction. Development of an abscess produces fever and leukocytosis and local heat and inflammation are evident on examination of the septum. Treat-

ment is the same as for hematoma. Drainage maintained for several weeks may be necessary. Failure to drain or inadequate drainage may result in marked destruction of the cartilage and produce a "saddle-nose" external deformity. Because of the severity of the infection and the possibility of its extension to the intracranial cavity, antibiotics and/or chemotherapy are indicated.

Chronic hyperplastic rhinitis, one form of many acute and chronic infections which may involve the nasal cavities, is produced by constant irritation of the nasal mucosa by one or a combination of numerous agents. The epithelium thickens and fibrosis of the tunica propria occurs. This is prone to affect the erectile portions of the turbinal mucosa. Contraction of the fibrous tissue produces corrugations and irregularities in the thickened, swollen mucosa, causing obstruction to nasal respiration and to sinus drainage. The best treatment is to prevent the changes from occurring by eradicating the cause, for after fibrosis is established, the changes become irreversible. Surgical correction is then necessary and is accomplished by removing all, or the affected part, of the turbinates involved or by destroying the thickened tissue by actual or high-frequency cautery. Introduction of a cautery needle submu-

tion

A rather rare cause of nasal obstruction is *atresia* of either the anterior or posterior nares. This is usually congenital but may be acquired as a result of syphilis, tuberculosis or injury. The anterior atresias are membranous and those involving the posterior choanae are bony or membranous, or both. They are either bilateral or unilateral and, if unilateral, may escape detection. The treatment is surgical removal. The approach to the posterior atresias is difficult and the surgery is often unsuccessful, owing to the difficulty of removal and the tendency for the surgically created opening to close.

Spontaneous hemorrhage from the nose, or *epistaxis*, is a common and frequent occurrence which is often difficult for the surgeon to bring under control and, if prolonged, results not only in considerable blood loss but almost invariably produces some degree of shock, and an emotionally disturbed and frightened patient. The commonest site from which bleeding occurs is at the anterior inferior end of the nasal septum, the bleeding is due to the rupture of a

though headache is sometimes a prominent symptom in sinus disease, any attempt to diagnose the sinus involved by the location or character of the headache can be most inaccurate.

Redness and swelling may occur over any acutely involved sinus which lies close to the skin and is frequently seen at the inner angle of the orbit in acute ethmoiditis in infants or children. Edema can occur without inflammation.

Transillumination gives additional diagnostic information about the frontal and maxillary sinuses but cannot be applied to the ethmoid or sphenoid sinuses because of their anatomic location. The light fails to pass through, or passes through with diminished intensity, those sinuses which are involved. Transillumination is affected not only by the condition of the sinus itself, but also by the thickness of the bone and other tissues through which the light must pass.

Failure of a frontal sinus to transilluminate may indicate a small or absent sinus rather than infection. Transillumination is presumptive evidence of normality or abnormality of the sinus thus examined and is valid only when considered with the objective clinical findings and the history. It is of questionable value in children, and in adults additional x-ray evidence is often necessary to determine the location and the severity of involvement of the diseased sinus.

The x-ray evidence of sinus disease must also be interpreted in connection with the history and the clinical findings. The instillation of radiopaque oil into the sinuses, followed by x-ray examination, outlines the cavity of the sinus and gives valuable information concerning the thickness of the lining membrane and the presence of a polyp, cyst or tumor. The oil is introduced into the ethmoid cells by the displacement technique of Proetz and into the others by cannulating the natural opening, whenever possible.

If, after these diagnostic procedures, the diagnosis is still uncertain, it may be necessary to irrigate the sinus to obtain direct washings for study. This procedure should also be done through the natural opening, if conditions permit.

The complications of sinusitis may vary from some inconsequential local condition to the most desperate intracranial or systemic involvement. The diseased sinus may act as a focus of infection or the infection may spread by direct extension through continuity of structure, along fascial planes, through

dehiscences of the bony walls, along perineural sheaths and by the blood and lymph streams. Thrombophlebitis of a perforating vein is common and infection may reach the general circulation in the form of bacteremia.

Optic neuritis and retrobulbar neuritis not infrequently follow infection of the ethmoid or sphenoid sinuses, either by direct extension of the infection, by vascular congestion secondary to the sinusitis, by pressure on the optic nerve by bone or by periosteal changes induced by the sinus infection. Toxemia may produce loss of vision when the sinus serves as a focus of infection.

Orbital cellulitis and orbital abscess are commonly produced by extension of infection from the sinuses, most commonly from the ethmoid cells or the maxillary sinus. They are most often seen in children. The infection reaches the orbit through a dehiscence in the wall or it is due to thrombophlebitis. Pus may burrow forward along the periorbital and present in the lid without involving the orbital contents or burrow posteriorly along the periorbital to the sheath of the optic nerve and produce intracranial involvement. If an orbital cellulitis occurs, thrombophlebitis of the orbital vein may result and the infection extend to the cavernous sinus. Other vascular channels can be involved by the same mode of extension.

Osteomyelitis of the skull may result from the spread of infection, usually by thrombophlebitis, into the bones of the calvarium. The outer table of the skull usually breaks down first, resulting in the formation of a subperiosteal abscess. Breaking down of the inner table does occur and an intracranial complication results. Necrosis of the bone of the roof cells of the ethmoid labyrinth not uncommonly occurs with direct extension of the infection into the anterior cranial fossa. Meningitis and brain abscess are the common intracranial complications.

Respiratory system complications are a common result of sinusitis and range from tonsillitis, pharyngitis and laryngitis to bronchitis, bronchiectasis, asthma and lung abscess. Generalized systemic complications and various forms of renal involvement can sometimes be traced to an active sinus infection.

The use of antibiotics and/or chemotherapy has had a pronounced effect on both the medical and surgical treatment of sinus disease. When this therapy is employed, the attack of acute sinusitis usually subsides quickly with much less deleterious effect on the sinus mucosa than was formerly obtain-

sinus disease is markedly influenced by the presence of conditions in the nose or sinuses which interfere with drainage and ventilation of the sinuses through their natural openings. The sinuses may become infected when no such obstruction exists, if the invading organism is of particular virulence or if the body resistance of the host is lowered. Chronic sinus disease, however, is not so apt to develop in those sinuses which suffer no interference with aeration and drainage.

The most commonly encountered obstructive lesions are a deflected nasal septum or a septal spur, an enlarged or cystic middle turbinate, nasal polyps or other nasal tumors, foreign body and chronic congestion of the nasal mucosa and nasal turbinates secondary to a chronic tonsil, adenoid or nasopharyngeal infection.

Obstruction in the region of the middle turbinate is of particular significance, owing to the fact that the frontal, maxillary and the anterior ethmoid cells drain into a relatively restricted area of the middle meatus, and infection of one or all of these sinuses may result.

Allergic rhinitis is often followed by secondary sinusitis, owing to blocking of the sinus ostia by the marked changes in the nasal and sinus mucosa. The floor of the maxillary sinus is in direct relation to the roots of the upper teeth and dental sepsis may extend to that sinus or infection may be introduced when the sinus cavity is unavoidably or accidentally opened during the extraction of an upper tooth. Trauma to the bony framework of the sinuses is increasingly common and the disruption produced by fractures and penetrating injuries is often followed by a severe infection. Destructive new growths originate in or extend into the sinuses and the effect of the tumor on the mucosa, plus the interference with drainage, results in sinusitis which may be the complaint which leads to discovery of the tumor.

It is generally agreed that some factor, or factors, other than the presence of bacteria is necessary to produce sinus disease. In trauma, the injury to the sinus plus the introduction of bacteria may be sufficient. The obstructive lesions have been noted in sinus disease, if the etiologic basis is not evident, more obscure factors must be considered. These include general debility, lowered resistance from emotional stress, overwork or exposure; dietary deficiencies, endocrine imbalance and hereditary or acquired pathologic and anatomic factors. With or without

the presence of any of these contributing factors, the most common cause of sinus infection is bacterial invasion of the sinus following the common cold.

The pathologic changes occurring in the mucous membrane lining the affected sinus show a wide variation and thus there is a tendency to complex classifications. The changes can be conveniently and simply grouped into four types: *acute edematous*, *acute suppurative*, *chronic suppurative* and *chronic hyperplastic*. In the acute changes, the membrane is hyperemic, edematous and covered with a fibrinous exudate. The degree of these changes can further be classified as catarrhal, mucopurulent and gangrenous. Chronic suppurative changes can be described as edematous, infiltrative, fibrotic, cystic and degenerative. Any combination of these changes may exist in the same diseased membrane. Ulceration and involvement of the underlying bone are not unusual in the chronic suppurative type. This may lead to the formation of fistulous tracts which, by their extension, may cause serious intracranial, ocular or dental complications.

The chronic hyperplastic form is characterized by marked thickening and edema leading to the formation of polypoid masses. This polyp formation is common in the maxillary sinuses and the ethmoid cells. The chronic hyperplastic form is often associated with an allergic rhinitis, but the exact relationship between the two conditions has not yet been finally determined.

The symptoms of infection of any sinus depend upon the sinus involved, and upon the character, duration and intensity of the infection. In general, the more acute the infection the more typical the symptoms. Acute sinusitis is accompanied by pain, fever, general malaise, a feeling of fullness or pressure in the head or face and serous, mucopurulent or purulent discharge from the nose. Tenderness and pain on pressure over the involved sinus are usually present in the acute phase, but seldom in the chronic. The diagnosis is made from the history and the objective clinical findings. If the sinus is draining, the source of the drainage can usually be seen. Pus in the middle meatus indicates involvement of the frontal or maxillary sinuses or of the anterior ethmoid cells, alone or in any combination. Discharge in the superior meatus or in the sphenoidal recess, which can be seen by posterior rhinoscopy, is indicative of posterior ethmoid or sphenoid involvement. Al-

sisted conservative treatment and repeated irrigations often respond favorably to this treatment.

A more extensive operation is indicated when the entire membrane lining the maxillary sinus must be removed because of marked hyperplastic, polypoid or cystic changes or when a chronic infection has produced a thickened, fibrous, ulcerated, suppurating or degenerated mucous membrane. The operation most frequently used for this purpose is the Caldwell-Luc procedure. An incision through the mucous membrane and periosteum in the sulcus between the gum and the upper lip above the bicuspid and first molar teeth allows the bone of the canine fossa to be exposed. The anterior wall of the sinus is perforated here and the greater part of the wall removed. The lining membrane and any other contents of the cavity are removed and an opening is made through the medial (nasoantral) wall of the sinus into the inferior meatus of the nose. Epithelization of the denuded bony walls is accomplished by regrowth of epithelium from the nasal cavity through the antrotomy and the natural openings.

The surgical attack on a diseased frontal sinus may be done by either an intranasal or an external approach. The removal of the anterior end of the middle turbinate followed by irrigation of the sinus through the nasofrontal duct is effective treatment and should be tried before more extensive surgery is decided upon. If this treatment proves to be insufficient, the nasofrontal duct may be enlarged by an intranasal procedure. The middle turbinate is fractured toward the septum to increase the space in the middle meatus. Bone is removed by biting forceps passed upward through the anterior ethmoid cells to the crista nasalis and the floor of the frontal sinus is entered. Ethmoid cells lying behind the nasofrontal duct are removed in the same manner and all irregularities and protecting edges are smoothed. In this procedure, the medial wall of the ethmoid capsule is avoided, since it is a continuation of the cribriform plate, fracture of which could allow extension of infection to the cranial cavity.

Frontal sinus disease is often so severe, with fistula formation, intracranial or orbital complications, excessive bone necrosis or mucocele formation that an external approach is required to expose and eradicate the pathologic process. The least extensive external approach consists of removal of part of the anterior wall, essentially a trephining,

and insertion of an external drain. Its application is limited; it is used most often in patients with acute fulminating frontal sinusitis with pus under pressure in whom serious consequence may result if drainage is not prompt and adequate.

The Lynch frontoethmoid operation is a safe and effective external approach to the frontal sinus for patients in whom extensive surgical interference is required. The procedure gives excellent exposure not only of the frontal sinus and the anterior ethmoid cells but, with modifications, of the posterior ethmoid cells and the sphenoid sinus as well. In advanced disease of the frontal sinus, the anterior ethmoid cells are almost invariably diseased. They should be removed at the time of the operation on the frontal sinus and in adults these two procedures are almost always combined. Excellent visualization of the surgical area is obtained by this approach. Exposure is obtained by an incision made through the eyebrow which extends medially well down over the nasal process of the superior maxilla. The soft tissues are retracted down and away from the bone. The floor of the frontal sinus and the contents of the sinus cavity are removed. The nasofrontal duct is enlarged and the anterior ethmoid cells are everted. If indicated, the medial wall of the orbit can be entered and the entire ethmoid labyrinth and the middle turbinate removed. This gives access to the sphenoid sinus which can be opened if necessary.

In cases of orbital abscess or when an external fistula from the ethmoid has developed, particularly in children, external drainage of the ethmoid labyrinth alone may be indicated. The incision is the same as for the frontoethmoid operation and care is taken to avoid injury to the lacrimal sac and ducts during elevation and retraction of the soft tissues. The ethmoid sinus is entered through the lamina papyracea and sufficient exposure is obtained for removal of both anterior and posterior cells. External drainage is maintained until all drainage ceases.

Intranasal operations on the ethmoid labyrinth require surgical skill and, because the ethmoid is less frequently operated upon than in former years, many surgeons prefer the external approach because of easier visualization and orientation. When the intranasal approach is employed, the middle turbinate may be removed in whole or part to allow better visualization of the operative field. The ethmoid labyrinth is entered through the ethmoid bulla and the cells re-

able. The rapid and more complete clearing of the acute phase results in fewer cases entering the chronic state of infection and the need for surgical interference is of less frequent occurrence. The danger of an early, severe complication is abated and in the longer period available for conservative therapy, many cases go on to complete resolution that would have required surgery in the past. Antibiotic therapy and chemotherapy are not without danger. Symptoms may be masked, the infection may become indolent and confusion and indecision for the necessity of surgical interference may result.

The development of strains of bacteria resistant to antibiotics is increasing. Antibiotic therapy and chemotherapy alone are not adequate in most cases of chronic sinusitis. The use of these forms of therapy does not supersede the basic principles involved in the treatment of sinus disease. Measures necessary to improve ventilation and establish free drainage of the diseased sinus are still required.

Local treatment during an acute attack consists of shrinking and decongesting the nasal mucosa and turbinates by the application of vasoconstricting agents, such as ephedrine compounds, Adrenalin or cocaine. These are applied to the nasal structures by spraying or placing cotton tampons moistened with the substance in the region of the middle meatus. Mild suction, cautiously applied, is helpful. Some form of heat during the acute phase gives comfort to the patient. General supportive measures and symptomatic treatment are given as required. As the acute stage of the infection passes and fever subsides, the sinus may be irrigated if resolution seems delayed. This irrigation can, in many subjects, be done by cannulating the natural opening of the sinus. If the maxillary sinus cannot be cannulated easily through its ostium, the nasoantral wall beneath the inferior turbinate can be pierced by an antral trocar and the sinus irrigated. Warm normal saline solution is a suitable irrigating agent. If desired, an antibiotic solution can then be instilled and left in the sinus. Repeated washings may be necessary.

When frontal and maxillary sinusitis co-exist, treatment and irrigation of the maxillary sinus may lessen swelling in the middle meatus sufficiently to allow the frontal sinus to drain normally. Irrigation of the frontal sinus may be performed by cannulating the nasofrontal duct unless bony obstruction or septal deviation prevents the procedure. The

frontal sinus does not often require lavage because the nasofrontal duct opening at the bottom of the sinus promotes dependent drainage.

The *sphenoid sinus* may be irrigated through the natural ostium, although it may be necessary to first remove an obstructing part of the middle turbinate. If the natural ostium cannot be entered, the anterior wall can be punctured.

The *ethmoid sinuses* cannot, in actuality, be irrigated, but secretion and exudate can be displaced by the Proetz technique. With the head tilted back, 0.25 per cent ephedrine in saline solution is introduced into the nose and nasopharynx. Intermittent negative pressure is exerted by an instrument devised for the purpose and the ephedrine solution enters the ethmoid cells and the sphenoid sinus, displacing any secretion or exudate in those sinuses.

No surgery of the sinuses is attempted during the acute phase of infection unless a complication of some seriousness threatens. In such case, the surgery done is the least necessary to solve the particular problem and extensive or definitive surgery should not be undertaken.

The surgical treatment of inflammatory sinus disease includes those procedures necessary to correct any intranasal deformities which interfere with sinus drainage, and/or opening of the sinus involved for drainage or removal of its contents by either an intranasal or external surgical approach. The decision to perform sinus surgery and the choice of the procedure to be done depend on the location and type of involvement and are influenced by the age, physical condition and emotional status of the patient.

The simplest surgical procedure for draining and ventilating the maxillary sinus, excepting sinus irrigation, is the creation of a permanent opening into the sinus through the nasoantral wall in the inferior meatus of the nose. By this antrotomy, or antrum window operation, an opening of generous size is created. Care is taken to avoid injury to the nasolacrimal canal which opens into the inferior meatus under the anterior end of the inferior turbinate. The sinus cavity can be directly inspected through the opening or a nasoscope can be introduced through the aperture and all areas of the sinus inspected for pathologic changes. It is possible to remove small amounts of diseased tissue through the new opening. Many cases of chronic maxillary sinusitis which have re-

rior portion of the ring. In addition to these well defined lymphoid structures, there is a considerable amount of irregular-shaped and -sized lymphoid tissue scattered about on the posterior pharyngeal wall, which may undergo rather pronounced hyperplasia under certain conditions.

The *adenoid* is present at birth but undergoes atrophy at puberty, although remnants are often found in adults. It consists of masses of lymphoid cells supported by a fibrous connective tissue framework. The stroma forms pockets or spaces, each one of which is called a lymph follicle. The total mass is divided by deep vertical clefts, or fissures, the central one of which ends in a fossa known as the median recess. The clefts in the adenoid mass run so deep that, upon removal, the mounds between the clefts can be separated like the leaves of a book.

The *faucial tonsils* are formed of the same type of lymphoid tissue supported by a connective tissue reticulum, but, where the adenoid contains clefts, or folds, the faucial tonsil is canalized by epithelial ingrowth to form a complex system of crypts. The openings of the crypts on the surface of the tonsil are seen as small indentations and the crypts collect and hold cellular debris, inspissated secretion and dead and viable bacteria. Exudate in these crypts during an acute inflammation gives the surface of the tonsil a characteristic follicular appearance. The tonsil lies in a fossa created by the anterior and posterior pillars and the so-called capsule of the tonsil rests against the superior constrictor muscle. The lingual tonsil has the same characteristic internal structure as do the adenoid and faucial tonsils but does not develop clefts or branching crypts.

The chief functions of the pharynx are concerned with respiration, deglutition, voice resonance and articulation. There is a minor gustatory function owing to the presence of a few scattered taste buds. Because of the location of the orifices of the eustachian tube, the pharynx is also concerned in hearing. It is probable that there is a considerable immunologic function, since the lymphoid structures in the pharynx are a part of the reticuloendothelial system and form a first line of defense against invasion of the body by infection. Phagocytic activity of the cells probably plays a part in natural and acquired immunity.

Inflammatory disease of the lymphoid structures of the pharynx, or spread of such infection to contiguous or distant organs, may necessitate surgical therapy to eradi-

cate the disease. The faucial tonsil is representative of all the lymphoid structures composing Waldeyer's ring as concerns reaction of this tissue to infection and for practical purposes the description of acute tonsillitis can stand for acute infection of the adenoid, the lingual tonsil and the scattered pharyngeal follicles. The main difference lies in the symptoms and the complications produced.

Acute tonsillitis is characterized by redness, pain, pain on swallowing, fever and leukocytosis and general malaise. There is marked hyperemia and swelling of the tissue and small, punctate, yellow-white spots are scattered over the mucous membrane surface. In some subjects, pseudomembranes are formed. The bacteria commonly found are streptococci, pneumococci and staphylococci. The crypts of the faucial tonsil fill with desquamated epithelium, phagocytes and bacteria and pus may often ooze from the crypt.

The complications of acute tonsillitis include peritonsillar abscess, tonsillar abscess, toxemia, septicemia, endocarditis, arthritis, pneumonia, suppurative otitis media and nephritis. The infection may spread to the neck and produce a deep cervical abscess that can extend to the base of the skull or into the mediastinum.

The treatment of acute tonsillitis is medical and includes bed rest, adequate fluid intake and general supportive and symptomatic treatment. Hot normal saline throat irrigations or gargles are beneficial. The disease is self-limited, but severe systemic reaction or threatened complication is probably best treated by the administration of antibiotics or sulfonamides. Topical use of antibiotics is not helpful and may result in sensitizing the patient to the antibiotic so used.

Septic sore throat is an acute primary streptococcal infection of the pharynx and tonsils, and has a much more violent inflammatory reaction than does acute tonsillitis. There is a diffuse, fiery redness of the entire pharynx, tonsils and pillars and soft palate, and patches of gray pseudomembrane usually appear. The rapid formation of an inflammatory, edematous swelling with extension to the surrounding parts is typical of this disease. The exciting organism is a streptococcus of the beta hemolytic type. The condition sometimes occurs in epidemics and is often milk borne. There is high fever, prostration and toxemia. A skin rash may be produced as in scarlet fever, but the rash is more variable and less pro-

moved by one or a combination of several methods. The posterior, outer and upper angle of the posterior ethmoid cell is a region of extreme hazard because of its anatomic relations.

The intranasal approach to the sphenoid sinus is one of marked surgical risk. Perfect vision of the entire surgical field is necessary at all stages of the operation. The superior wall of the sinus is in close relation with the optic nerve, the pituitary gland, the brain, the lateral wall with the cavernous sinus, and the internal carotid artery. All obstructing conditions of the nasal septum and the nasal cavity must be corrected. The posterior half of the middle turbinate is removed and the posterior ethmoid cells everted. A sphenoid punch forceps or a sphenoid elevator is inserted into the ostium and the opening cautiously enlarged by removing part of the anterior wall. Exploring, curetting or packing the sinus is extremely hazardous.

THE PHARYNX

The pharynx is a musculomembranous tube, wide above and narrow below, extending from the basal portion of the occipital bone to the level of the sixth cervical vertebra. It communicates with five cavities: the right and left nasal cavities through the posterior choanae, the right and left eustachian tubes, the oral cavity, the vestibule of the larynx, and the esophagus. The musculature of the pharynx consists of three pairs of constrictor muscles: the superior, middle and inferior, and two pairs of elevator muscles, the stylopharyngeus and the palatopharyngeus. The constrictors are outer, circular muscles and the elevators are longitudinal, inner muscles, a reverse order of arrangement to that found in the esophagus.

The nasopharynx is that portion of the pharynx above the level of the soft palate, it is immobile except for the soft palate which, in contraction, forms a floor for the space. The oropharynx extends from the inferior border of the soft palate to the lingual surface of the epiglottis. The hypopharynx extends from the tip of the epiglottis to the esophagus. The anterosuperior part of the hypopharynx is often designated as the laryngopharynx.

The eustachian tubes open into the anterolateral wall of the nasopharynx just behind the posterior ends of the inferior nasal turbinates. Above and behind the tubal orifices the wall expands to form a cul-de-sac, the pharyngeal recess or Rosenmüller's fossa.

The wall here is in close relationship to the internal carotid artery.

The hypophysis cerebri develops as an evagination from the nasopharynx at a point in the midline high on the posterior wall. Rarely, a vestige of the stalk remains and forms a cyst, the pharyngeal bursa, which extends in the median plane to the pharyngeal tubercle of the occipital bone and lies under the mucous membrane. The adenoid develops in this area and the pharyngeal bursa, when it exists, lies immediately above and behind the median recess of the adenoid. When an adenoid remnant persists in an adult, the central cleft of the adenoid, which leads into the median recess of that structure, is often seen as a slitlike opening. This cleft may harbor infection and an abscess of the median recess can develop. This is known as *Thornwaldt's disease*. If a pharyngeal bursa exists and becomes infected, it is often erroneously diagnosed as *Thornwaldt's disease* and the two are often difficult to differentiate by examination. Since abscess of the median recess, or *Thornwaldt's disease*, lies in adenoid tissue, it can be opened by a probe, but the pharyngeal bursa, which lies behind the pharyngeal mucous membrane, requires incision to effect drainage.

The oropharynx opens into the oral cavity and is bounded above by the soft palate and laterally by the glossopalatine and pharyngopalatine muscles, constituting, respectively, the anterior and posterior pillars between which lie the palatine, or faucial, tonsils. The lingual tonsil is a collection of lymphoid tissue situated on the base of the tongue and is bisected by the glossopiglottic ligament.

The hypopharynx, that portion of the pharynx below the tip of the epiglottis, enlarges laterally into the pyriform sinuses. During deglutition, the larynx is raised and closed and the bolus is directed into the pyriform sinuses and on into the esophagus. The anterosuperior portion of the hypopharynx communicates with the vestibule of the larynx and is designated as the laryngopharynx.

The pharynx contains masses of lymphoid tissue so arranged as to form a ring about the pharynx. These masses form the combined structure known as *Waldeyer's ring*. The adenoid, or pharyngeal tonsil, in the nasopharynx forms the posterior portion, the palatine, or faucial, tonsil in the oropharynx forms the lateral part, and the lingual tonsil on the base of the tongue forms the ante-

occur in adults but is considered to be a disease of infancy and early childhood. Occurrence is usually preceded by an upper respiratory infection and the abscess is produced by infection and breaking down of a prevertebral lymph node. It can be of tuberculous origin. The symptomatology is that of an upper respiratory infection followed by dysphagia and inspiratory dyspnea. Nursing or feeding is difficult and the voice is muffled or changed in quality. The location of the abscess may be high and easily visible above the base of the tongue or so low as to be difficult to palpate. Increasing dyspnea is a serious symptom and is due to pressure against the larynx and trachea by an abscess deep in the pharynx. This cause of respiratory obstruction in an infant must always be kept in mind. If the diagnosis is in doubt, a lateral x-ray view of the cervical region will show the location and size of the abscess, if one exists.

The prognosis is good if the condition is recognized. The abscess is incised and drained with the child on his back with the head extended and the shoulders elevated. The tongue is lifted up to expose the posterior pharyngeal wall and to insure an adequate airway. A mouth gag should not be used, since forcible opening of the jaw may rupture the abscess and result in a fatality. With good illumination and under direct vision, the abscess is incised and the contents are aspirated. Incision at the lowest point of the abscess may prevent it from burrowing lower in the pharynx. One draining usually suffices, although the wound may require reopening for two or three days.

The pharynx is at times involved by specific infections, such as syphilis and tuberculosis. Syphilis may be seen in any of its three phases. Tuberculosis involves the pharynx and its structures in both the acute and chronic forms. The first symptoms of leukemia, granulocytopenia, infectious mononucleosis, pernicious anemia and other blood dyscrasias often appear in the mouth or pharynx.

The pharynx is often involved by carcinoma. The primary sites occur in the nasopharynx, the tonsil, the lateral wall of the hypopharynx and in the laryngopharynx. Other tumors found in the pharynx include sarcoma, fibroma, papilloma, polyps, cyst and angioma. The pharynx is also subject to various sensory and motor neuroses.

Most foreign bodies which enter the pharynx pass on to enter the esophagus or the larynx and tracheobronchial tree. Those

which lodge in the pharynx proper are usually sharp-pointed objects, such as pins, tacks and small fish bones. These usually lodge in the faucial tonsil or the tonsil fossa, the lingual tonsil on the base of the tongue, or in the lateral pharyngeal wall behind the posterior pillar. Occasionally, one will lodge in the vallecula between the base of tongue and the anterior surface of the epiglottis. Careful search will reveal them and they can usually be grasped by an appropriate forceps and removed. Caution and skill are necessary in order that they are not dislodged and converted into an esophageal, laryngeal or pulmonary foreign body.

Pulsion diverticulum has its origin from the pharynx but is often referred to as of esophageal origin because of the symptoms it produces.

The surgical operation most frequently done on the pharynx is removal of the tonsils and adenoids. The diversity and severity of the complications produced by acute and chronic disease of the tonsils make the removal of these diseased organs of great benefit. Indiscriminate or incomplete removal by inadequately trained surgeons has no doubt caused harm to some individuals, but, when the proper indications exist, the operation can be recommended as being as necessary to the health and well-being of the individual as is the removal of a diseased organ elsewhere in the body.

The indications for tonsillectomy and adenoidectomy are usually quite evident. In children, gross hypertrophy is sometimes so great as to prevent nasal respiration and the tonsils meet in the midline, producing an actual block against the passage of food. The child is a poor eater and the obstruction to respiration, when prolonged, produces a typical "adenoid facies." The child tends to be dull and apathetic, nourishment is poor and general growth and development are delayed. Marked hypertrophy can develop without the stimulus of infection and constitutes a positive indication for surgical intervention.

Recurrent otitis media in children is most often secondary to disease of the adenoids and tonsils and the removal of these tissues has more chance of preventing and eradicating this complication than has any other single procedure. Control of the otitis media minimizes the incidence of future deafness and sharply reduces the chance of mastoid disease and its complications.

Persistent enlargement of the cervical glands which drain the tonsillar area is often

tracted. Since this infection is violent, and more apt to produce systemic complications than is acute tonsillitis, appropriate antibiotic and sulfonamide therapy should be given early and continued, if possible, until the patient is symptom free.

Acute infection caused by fusiform bacilli and spirochetes in combination frequently affects the pharynx and is known as *Plaut-Vincent's angina*, or *trench mouth*, when there is involvement of the mouth and gums. This infection rather typically produces ulcerations of the mucous membrane and pseudomembrane is often formed. Despite the ulcerations and the presence of pseudomembrane, the surrounding tissues usually do not show as severe involvement as occurs in acute bacterial pharyngitis. Examination of smears from the infected areas will usually establish the diagnosis.

Diphtheritic tonsillopharyngitis does not now occur frequently but, when it does occur, is most often seen by the pediatrician. It must be suspected in any pharyngitis with membrane formation and smears should be made for microscopic study. The onset may be mild with only slight soreness of the throat or the onset may be sudden with severe toxemia and prostration. Swollen, tender cervical lymph glands are usually found. The breath has a foul, peculiar odor. The throat may be red and no membrane present, but usually there are patches of adherent gray, yellow or greenish membrane that leave a bleeding, raw surface when removed, and which quickly re-form. Differentiating a true diphtheritic membrane from the pseudomembrane produced by the coccal forms of bacteria and by fusiform-spirochete infection may be difficult, particularly if there is ulceration under the pseudomembrane. The treatment of diphtheria is medical, except in those instances when membrane forms in the larynx, producing obstruction that may require tracheotomy for relief, or when the tonsils may require removal to eradicate a "carrier" state of infection.

Peritonsillar abscess occurs as a complication of acute tonsillitis. Several days after the onset of the acute tonsil infection, and frequently when the tonsillitis seems to be clearing, there is a return of pain and inflammation more severe than the original. Swallowing becomes difficult or impossible, the jaw can be opened only slightly and with great pain and speech becomes muffled and thick. Examination reveals a unilateral swelling near the upper pole of the tonsil involving the anterior pillar and the soft palate.

The tissues are shiny, fiery red and edematous. The uvula may be pushed to the opposite side and the usual landmarks of the area are obscured by the swelling. Fever may be absent. The abscess is produced by extension of the acute infection into the loose peritonsillar tissue, first as cellulitis and progressing to abscess formation. Administration of antibiotics in the cellulitis phase may prevent abscess development, but the complication not infrequently occurs during antibiotic or sulfonamide therapy for acute tonsillitis. During the stage of cellulitis, throat irrigations with hot normal saline solution should be given at frequent intervals. Incision at this stage is not wise, but, when an abscess is formed, surgical drainage is required. An incision is made through the anterior pillar or through the supratonsillar fossa until pus is reached. A blunt forceps is introduced through the incision to the abscess cavity and forcibly opened to enlarge the drainage tract. Relief is so immediate that the patient does not resent the momentary pain this procedure causes. Care is taken that the patient does not aspirate the pus. Peritonsillar abscess, or quinsy sore throat, does not often occur in children.

An abscess within the substance of the tonsil may follow or complicate acute tonsillitis but is of infrequent occurrence. In the acute process, the patient is toxic, the tonsil is large, hyperemic and firm but not tender to touch. The surrounding tissues are not markedly involved. The treatment is incision and drainage. A retention cyst of the tonsil occurs more frequently than an acute abscess and is found in a superficial area. It is probably produced by the closing off of a crypt.

A *lateral pharyngeal abscess* may be produced by acute tonsillitis or a peritonsillar abscess. The abscess forms external to the superior constrictor muscle, just lateral or posterior to the faucial tonsil. If posterior to the tonsil, it may bulge into the pharynx and be drained by incision through the pharyngeal mucosa. If lateral to the tonsil, removal of the tonsil will give access for draining through the pharynx. External drainage through the neck may be necessary. Such abscesses can extend along fascial planes to the base of the skull or to the mediastinum. Extension of a lateral pharyngeal abscess may require extensive external drainage of either the pharyngomaxillary fossa or the neck spaces.

Retropharyngeal abscess is a collection of pus behind the posterior pharyngeal wall anterior to the prevertebral fascia. It may

teeth, bits of tonsil or adenoid tissue, pieces of instruments, sponges and blood. General complications include thrombophlebitis and embolism, septicemia, otitis media and its complications, atelectasis, lung abscess, exacerbation of organic disease, meningitis and death.

TUMORS

The nose, nasal sinuses and the nasopharynx may be involved by benign or malignant tumors arising from any of the types of tissue found in, or going to make up, these structures. Included, therefore, are tumors derived from epithelium, cartilage, bone, connective tissue, lymphoid elements, endothelium, pigment cells and neural tissue. The same areas may be invaded by tumors extending from adjacent structures and, in rare instances, be the site of metastases from distant primary lesions.

Although the majority of the tumors encountered in the nose, sinuses and the nasopharynx are benign, any tumor in this area must be considered as malignant until proved otherwise. The gross appearance of the lesion can be very misleading. Malignant lesions frequently simulate the appearance of the simplest benign tumor common to the area. Certain tumors, although histologically benign, have malignant characteristics in that they erode or invade adjacent structures, produce destruction and deformity and result, ultimately, in death. The treatment necessary to eradicate a tumor of this type approaches or equals that required in the attack on a malignant one. These facts emphasize the importance of accurate diagnosis. Biopsy of the tissues is the only means of achieving proper identification and classification. Repeat biopsies are necessary when clinical judgment is not satisfied by the first or subsequent tissue reports. The specimen of tissue removed should be generous.

The symptoms of tumor in the nose, sinuses or the nasopharynx depend largely on the location, size and growth characteristics of the neoplasm. The most usual symptoms include nasal obstruction, nasal discharge, pain referred to the teeth and various areas of the head, paresthesia of the cheek, bloody discharge or hemorrhage from the nose or nasopharynx, eye or visual disturbances and external deformity. Most of the above symptoms depend on erosion, pressure by or invasion of the tumor and are, unfortunately, late symptoms. Although many of these symptoms occur after the tumor has reached considerable size or extent, none of them

gives any hint of the pathologic condition responsible for symptoms which are of such common and widespread occurrence. Neither are the symptoms helpful in determining the site of origin, since primary nasal tumors invade the sinuses, and tumors arising in the sinuses may cause no symptoms until they encroach on the nasal cavity. Tumors of the maxillary, frontal and ethmoid sinuses may invade the orbit and produce visual disturbances. Sphenoid sinus neoplasms can also produce visual symptoms by pressure on the optic nerve or by invasion of the cranial vault.

BENIGN TUMORS OF THE NASAL CAVITY AND PARANASAL SINUSES

By far the most commonly encountered benign tumor of the nasal cavity and of the paranasal sinuses is the mucous polyp. These are usually multiple, but they occasionally occur as a solitary growth. A question remains as to whether these are true tumors or only edematous hypertrophies of the nasal or sinus mucosa resulting from frequent congestions and a rarefying osteitis of the underlying bone. The maxillary and ethmoid sinuses are most often involved in this type of reaction. Polyps from these sinuses may present in the nasal cavity, or even in the nasopharynx, attached to their point of origin by a long narrow pedicle.

A polyp has the appearance of a smooth, rounded, grayish-pink, slimy tumor. It is covered by respiratory epithelium and many eosinophils and blood vessels are found in the loose, edematous stroma. Polyps are classified as edematous, fibrous, angiectatic, glandular or cystic, depending on the relative amounts of these elements making up the stroma. The appearance and consistency of the polyp vary with the type. The edematous polyp is the most common.

The symptoms produced by nasal polyps are nasal obstruction, profuse watery to purulent discharge, sneezing and loss of the sense of smell. The severity of the symptoms depends on the number and size of the polyps. Headache as a result of the severe nasal congestion is common.

The treatment of nasal polyps is surgical. Medical treatment alone is not effective. In all cases, infection must be cleared, allergies controlled or eliminated and other irritants avoided. The use of corticosteroids appears to be of benefit in some cases, but, since they are not universally helpful and their use is not without certain hazards, they cannot be recommended for routine treatment. Re-

an indication of active tonsil infection, which may require tonsillectomy. The occurrence of a peritonsillar abscess is an absolute indication for tonsillectomy, since the abscess is prone to recur with subsequent attacks of tonsillitis and because the potentials are so serious. The crypts in some tonsils become enlarged and contain so much debris and bacteria that, while not producing marked infection of the tonsil, they are responsible for foul breath and local irritation. Tonsillectomy is the only sure means of correcting such a condition.

In addition to these rather clear-cut indications are many lesser indications which vary with the feelings and beliefs of the surgeon, pediatrician or internist concerned. They are usually based on the effect of removal of diseased tonsils, or tonsils and adenoids, on respiratory tract and lung disease, rheumatic fever, arthritis, pyelitis, nephritis and any other conditions to which the tonsil infection is felt to be a contributing factor.

Recently, the correlation between removal of the tonsils and adenoids and increased susceptibility to poliomyelitis has been under

less than the attack rate in the general population. There is evidence that if poliomyelitis develops soon after removal of the tonsils and adenoids there is a possibility of its being due to the operation. This possibility is of little importance. Despite the vaccine the operation should not be done when the incidence of poliomyelitis in the community is high.

Conscientiously to recommend surgical removal of the tonsils as a procedure which will benefit the patient is a decision arrived at after obtaining a careful history and a thorough physical examination to exclude the possibility of other diseases which may be responsible for the symptoms, and after a period of observation of the course of the tonsil disease. The physical appearance of the tonsil, in most cases, is the least important factor in making the decision.

The technique of surgical removal of the tonsils and adenoids has infinite variations and modifications, but, in general, these fall into two types: that of dissection and snare, and the guillotine method. There is a choice as to the positioning of the patient during the operation, each having exponents for its superiority.

In the dissection and snare method, the tonsil is grasped by a tonsil forceps and dissected away from the peritonsillar tissues by blunt or sharp dissection with knives or scissors or other instruments devised for this purpose. After being freed superiorly, and from the anterior and posterior pillars, a cold wire snare is passed over the tonsil and it is severed at the base by closing the snare. The dissection is against the so-called capsule of the tonsil and avoids the aponeurosis covering the fibers of the constrictor muscles.

The guillotine method utilizes an instrument incorporating a ring which can be closed by a blade or cold wire snare. The tonsil is pushed through the ring, held by a blunt hemostatic blade and then severed by a sharp blade, or the tonsil is engaged by the snare as it is pushed through the ring and then severed from its attachments by slowly closing the snare. Proponents of the guillotine method cite lessened bleeding and less trauma to the surrounding tissues as its main advantages.

The adenoid is removed by the use of an adenotome or is scraped from its attachments by special curets. The adenotome is a boxlike instrument designed to fit the nasopharynx; the lower side of the adenotome can be closed by a flexible cutting blade. The adenotome is placed over the adenoid with the blade opened, pressed down firmly and the adenoid severed by closing the blade. The closed instrument prevents pieces of adenoid tissue from entering the lower airways. Lateral extensions and small remnants can be removed by curetting, or by using punch forceps.

During the performance of the operation, one of the greatest responsibilities of the surgeon is the maintenance of a clear airway at all times. Another as important, and interrelated, is the control of hemorrhage. Inspired blood is one of the frequent causes of embarrassed respiration. A free and clear airway at all times during the operation is of primary importance in preventing the occasional, but too frequent, surgical death. It is for this purpose that intubation of the larynx to administer the anesthesia has been recommended.

The complications of tonsillectomy and adenoidectomy include hemorrhage at the time of the operation or shortly after; secondary hemorrhage many hours or days postoperatively, edema of the palate and uvula; acute inflammation with delayed healing or more serious complication; pulmonary foreign body from the inspiration of

teeth, bits of tonsil or adenoid tissue, pieces of instruments, sponges and blood. General complications include thrombophlebitis and embolism, septicemia, otitis media and its complications, atelectasis, lung abscess, exacerbation of organic disease, meningitis and death.

BENIGN TUMORS OF THE NASAL CAVITY AND PARANASAL SINUSES

By far the most commonly encountered benign tumor of the nasal cavity and of the paranasal sinuses is the mucous polyp. These are usually multiple, but they occasionally occur as a solitary growth. A question remains as to whether these are true tumors or only edematous hypertrophies of the nasal or sinus mucosa resulting from frequent congestions and a rarefying osteitis of the underlying bone. The maxillary and ethmoid sinuses are most often involved in this type of reaction. Polyps from these sinuses may present in the nasal cavity, or even in the nasopharynx, attached to their point of origin by a long narrow pedicle.

A polyp has the appearance of a smooth, rounded, grayish-pink, slimy tumor. It is covered by respiratory epithelium and many eosinophils and blood vessels are found in the loose, edematous stroma. Polyps are classified as edematous, fibrous, angiectatic, glandular or cystic, depending on the relative amounts of these elements making up the stroma. The appearance and consistency of the polyp vary with the type. The edematous polyp is the most common.

The symptoms produced by nasal polyps are nasal obstruction, profuse watery to purulent discharge, sneezing and loss of the sense of smell. The severity of the symptoms depends on the number and size of the polyps. Headache as a result of the severe nasal congestion is common.

The treatment of nasal polyps is surgical. Medical treatment alone is not effective. In all cases, infection must be cleared, allergies controlled or eliminated and other irritants avoided. The use of corticosteroids appears to be of benefit in some cases, but, since they are not universally helpful and their use is not without certain hazards, they cannot be recommended for routine treatment. Re-

removal of the polyps by a cold wire snare under light topical anesthesia gives immediate relief from the symptoms. In severe or long-standing involvement the sense of smell may remain impaired or lost. Removal of polyps usually needs to be repeated at varying intervals of time. Severe involvement of the sinuses may require extensive sinus surgery with complete removal of the diseased membrane.

The importance of the polyp as a nasal and sinus tumor does not rest in its frequency of occurrence but in the tendency of malignant conditions to induce a polypoid tissue response and simulate the polyp in appearance. All nasal polyps removed surgically should be submitted to microscopic examination. Malignancy is so often discovered in supposedly simple nasal polyps as to not only warrant, but require, such examination.

Primary fibroma, osteoma and chondroma of the nasal cavity are not common. Small papillomas, which are actually cutaneous warts, occur at the mucocutaneous junction in the nasal vestibule. Their location leads to constant irritation and they should be removed by electrosurgery. Papilloma durum, which is a true papilloma, occurring in the nasal cavity requires differentiation from a papillary carcinoma. Complete removal is required and the tissue must be examined microscopically for malignant changes. If these papillomas are widespread, even though they are benign, their removal should be followed by irradiation.

Syphilis and tuberculosis produce nasal lesions which require biopsy for identification.

Rhinoscleroma, a granulomatous disease rare in this country, produces nasal tumors.

Extreme hypertrophy of a turbinate, or a cystic or pneumatized turbinal bone, may cause an obstructing mass which requires differentiation from a neoplasm.

The benign tumors common to the paranasal sinuses are the mucous polyp, osteoma, fibroma, angioma, papilloma, cyst and mucocele. The pathology of these tumors is identical no matter which sinus is affected. The symptoms depend on the size, primary location and the adjacent structures involved.

Most benign tumors except nasal polyps, which tend to occur bilaterally, affect only one nasal cavity. Despite this, a growth obstructing one nasal cavity requires a provisional diagnosis of malignancy because unilaterality is a characteristic of carcinoma of the nose and the accessory sinuses.

Mucous polyps, most common to the ethmoid and maxillary sinuses, may block sinus drainage and result in suppuration.

If these tumors are present in the nasal cavity, they produce the same symptoms as nasal polyps. Osteoma does not produce symptoms unless the tumor occludes the sinus ostium or becomes large enough to produce pressure on a sinus wall. The frontal sinus is a very common site for osteoma. The ethmoid and maxillary sinuses seem to be less often involved. Papilloma durum requires thorough removal and tissue examination. Cysts, other than those produced by degenerated polyps, are usually of dental origin. These cysts usually grow rapidly and may erode a sinus wall or produce deformity of the hard palate or face. The surgical approach necessary for their removal depends on their location.

The frontal sinus, and less often the ethmoid sinus, may become involved by a mucocele. A mucocele is not a true tumor but is a retention cyst produced by a closure of the sinus ostium with the accumulation of secretions and exudate within the mucosal lining of the sinus cavity. Gradual distention leads to erosion of the sinus wall and, in both the frontal and ethmoid location, the orbit may be encroached upon with displacement of the eyeball downward and outward. This produces diplopia which may be the only symptom from which the individual seeks relief. The treatment is surgical removal of the diseased tissue by an external approach and re-establishment of normal sinus drainage.

The sphenoid sinus is most often affected by mucous polyps or by an osteoma. These may produce symptoms of suppuration or cause pressure which can result in optic neuritis or even produce exophthalmos.

MALIGNANT TUMORS OF THE NASAL CAVITY AND THE PARANASAL SINUSES

Malignant conditions of the nasal cavity and of the accessory nasal sinuses should always be considered to exist as a single entity. The characteristics of the disease make it highly improbable that one structure is involved without some involvement of the other and the successful eradication of the tumor may depend on this concept. For all practical purposes, malignant disease of the nose and sinuses implies carcinoma. All other varieties of malignant tumors found in these areas constitute a very small percentage of the total, as little as 1 per cent in some series of cases. The sarcomas constitute

the majority of the small percentage not carcinomas.

The symptoms produced by malignancy occurring in this area are not unusual or much different from those produced by a number of benign nasal, sinus or dental diseases. The basic symptoms are obstruction to nasal breathing, nasal discharge and nasal bleeding. In addition, there may be headache or pain referred to various areas of the head, face or to the teeth. Sinus suppuration is common and may have led to repeated sinus lavage. Not infrequently there have been multiple tooth extractions in an attempt to relieve the dental pain. None of the symptoms can be considered to be early since each depends on the enlargement of the tumor or on the erosion or invasion of other structures by the tumor. Fortunately, most carcinomas of these areas develop slowly and metastasize infrequently or late in their growth. The symptoms are certainly no indication of the extent of involvement or of the primary site of the lesion.

In sarcomatous involvement of the nose or sinuses, the prognosis depends upon the type of the tumor and the extent of involvement. Biopsy may show it to be a spindle cell, large or small round cell or osteoblastic, or lymphosarcoma, melanosarcoma, fibrosarcoma, chondrosarcoma or rhabdomyosarcoma. The only effective treatment is early and complete removal. Some of the sarcomas are highly radiosensitive and respond so well to irradiation that it is the treatment of choice. With the more radioresistant sarcomas, the best results are obtained by a combination of surgery and irradiation.

Just as the term malignant disease of the nose and paranasal sinuses implies carcinoma, carcinoma of the sinuses implies involvement of the maxillary or ethmoid sinuses. Primary malignant growth in the frontal sinus is rare. Carcinoma of the sphenoid sinus is also rare and, when it does occur, is almost always found in an advanced state with extension to the sella turcica or into the cranial vault. The location of the sphenoid sinus makes the surgical approach in this type of involvement extremely hazardous and impractical and irradiation of this area has not proved a satisfactory mode of treatment. Carcinoma of the ethmoid sinus tends to involve surrounding structures early in its development. This characteristic compromises the chance of recovery no matter what the mode of treatment.

The diagnosis of carcinoma of the sinuses is too often made in the late stages of the

disease. This delay in diagnosis may be due to symptoms that direct attention to other areas or that resemble symptoms of benign disease. It may be entirely due to the late development of the symptoms or to the failure of the individual to present himself for care. In these cases, the tumor may have produced external deformity or metastases. Diagnosis by x-ray examination is often made only after bone destruction has occurred. Any tumor found on x-ray examination must be suspect and studied by follow-up films. Of all abnormal densities in sinus x-rays, only osteoma produces a density greater than that produced by carcinoma. Tomographic studies are helpful in determining the extent of tumors which have spread beyond their primary location. Exploration and biopsy should be done immediately in any case when the diagnosis is in doubt. Biopsy is the only means of differentiating the benign from the malignant tumor. Repeated biopsies, with specimens being taken from several representative areas, must be the procedure when clinical judgment is not satisfied by a negative report. The ubiquitous mucous polyp must not be overlooked as possibly malignant.

The most commonly encountered carcinomas of the nose and paranasal sinuses are of the squamous cell variety which vary from slow growing to highly anaplastic types. An occasional adenocarcinoma is encountered.

The successful treatment of carcinoma of any organ is never easy, but when the growth occurs in the sinuses it is particularly difficult because of the preponderance of bone and the relative scarcity of soft tissue. While the bone does act as a barrier to extension of the neoplasm it also quickly becomes infiltrated with tumor. Because of the great variation in the manner in which these tumors develop, grow and invade, there can be no real standardization of treatment. The proper attack must be decided in each case and is best a team decision involving surgeon, x-ray therapist, pathologist and internist. The extent and type of the malignancy and the physical and emotional status of the patient are all factors which influence the ultimate choice of therapy. Treatment may be surgery alone, surgery preceded or followed by irradiation, or irradiation therapy alone. Surgical resection should not be attempted when there is no reasonable chance for complete removal of the tumor. If the case is clearly inoperable, nothing but palliative measures should be undertaken.

Contraindications to surgery vary, but the commonly accepted ones are destruction of the base of the skull, extensive bilateral involvement, involvement of the nasopharynx and distant metastases. Irradiation therapy alone will give better results in certain anaplastic radiosensitive tumors than can be obtained by surgery and should be the choice in such instances. Surgical removal, sometimes preceded and always followed by irradiation, gives the best results in the majority of cases.

The ideal surgery of any malignant growth is wide removal through normal tissue. This requirement can almost never be met in the surgical treatment of malignant disease of the sinuses. The approach may involve the site of the tumor and removal of the growth requires a certain amount of scraping and curetting. There is little doubt that these methods disseminate the cancer cells and may produce distant metastases. The use of electrosurgery (electrodissection and electrocoagulation) seals off blood vessels and lymphatics and should minimize the spread of cancer cells. The use of electrosurgery has made it possible to attack growths impossible to remove successfully by classical, or scalpel, surgery. In sinus cancer surgery, many surgeons believe it should be used to deal with all soft tissue, excepting the skin incision. Thorough diathermy coagulation of the postoperative cavity appears to increase the chances of complete eradication of the malignant growth. Postoperative irradiation, either by radium or external x-ray, should destroy disseminated cells and any microscopic remnants of tumor.

The first step in the treatment of malignant neoplasm of the sinus is surgical exposure of the lesion by whatever approach is necessary to obtain representative tissue for biopsy. The next consideration is the surgery necessary to provide drainage. Superimposed infection must be controlled prior to either definitive surgery or irradiation. Drainage operations should be done even if no infection exists, but treatment is to be by irradiation alone. This allows the escape of degenerated and sloughing tumor tissue and provides a window through which the response of the tumor to the therapy can be observed. It also permits the early detection of any recurrence. The common sites for these openings into the maxillary sinus are through the hard palate or sublabially through the canine fossa.

The surgical attack should aim at removal of the tumor with a margin of healthy tis-

sue. This demands an external approach with wide exposure and the sacrifice of normal structures if necessary. The surgical approaches described for the treatment of sinus suppuration and for exposure of benign tumors are completely inadequate in the treatment of malignant ones.

The surgical exposure should be made in the area of greatest involvement. For example, if the orbit is involved, the contents of the orbit should be eviscerated. This allows easy access to the frontal sinus above, the maxillary sinus below and the ethmoid and sphenoid sinus and the nasal cavity medially. If the hard palate is involved, removal of half of the hard palate gives easy access to the antrum and all other sinuses on that side. Even when it is not involved, many surgeons remove the hard palate as a routine part of the surgery. Irradiation should immediately follow surgery. External irradiation by x-ray is preferred in this country, but radium may be introduced into the tumor area if for any reason this should be preferable.

Irradiation should never be selected as the method of treatment with the idea that it is easier for the patient than surgery. It is very often the opposite. Irradiation produces reactions which are both painful and disfiguring. Radiation in cancerocidal doses results in definite morbidity. The pain and discomfort of radiation reaction, sloughing of the tumor and secondary infection can disable the patient for a long time. The pain of bone necrosis can be excruciating and may persist for months or years before sequestration finally takes place.

The final choice of the mode of treatment is not an easy decision and subsequent events may prove it not to have been the best. Extremely radical surgery may restore a person to an active, productive life, but it may also result in disfigurement which makes him a social outcast. Despite the probability of the patient surviving extensive surgery, it is the responsibility of the surgeon to choose the least surgery that will be effective. The surgery chosen, however, must be adequate to eradicate the malignant growth. There is no partial cure of cancer.

BENIGN AND MALIGNANT TUMORS OF THE NASOPHARYNX

Fibroma of the nasopharynx is an extremely vascular tumor found most often in young males between the ages of five and twenty. It is not of frequent occurrence. The tumor is so vascular that it should properly

be termed an angiofibroma. Though it is benign, it can present the most difficult surgical problems in its removal.

The tumor grows rapidly, filling the postnasal space. It may then extend into the nasal cavity or, by finger-like extensions, invade any of the sinuses or the cranial vault. These projections frequently attach at points of contact, making it appear that the tumor has multiple points of origin. It is composed chiefly of connective tissue with many thin-walled blood vessels which have almost no contractile layer. There is no true capsule. It arises by either a broad or pedunculated base from the fibrous layer of the prevertebral fascia and grows in the line of least resistance.

The symptoms are nasal obstruction and hemorrhage. The bleeding may be severe and persistent. If the tumor invades the skull, mental or ocular symptoms may result. Extension into the sinuses and the skull may separate the superior maxillary bones and produce exophthalmos, resulting in a "frog-face" deformity. A striking characteristic of these tumors is their tendency to disappear spontaneously in early adult life.

Differentiation from the adenoid mass, or from a mucous polyp, does not present much of a problem if the examination is careful. Sarcoma presents more of a problem and the microscopic differentiation is not always easy or certain.

Removal of these fibromas by classical surgical methods is difficult and hazardous. They cannot be avulsed because of their attachment to fascia or periosteum. Irradiation makes the tumor smaller and more accessible and, perhaps, lessens the tendency to hemorrhage. The introduction of electro-surgery has somewhat simplified the surgical problems posed by these tumors and the combination of preoperative irradiation and electro-surgery is the method of choice when surgery is necessary.

Although various types of sarcomas occur in the nasopharynx, the malignant growth most often encountered is the epidermoid carcinoma. Squamous cell, slow growing or highly anaplastic types and adenocarcinomas are all represented. The incidence of

slow growing and anaplastic types is about equal.

The symptoms depend on the size and location of the tumor. There may be no recognizable symptoms before the tumor reaches a large size or produces metastases. If the lesion is large enough, there is nasal obstruction. If the growth encroaches on the eustachian tube, there may be hearing loss and middle ear symptoms. Blood-tinged postnasal drainage is more common than frank hemorrhage. Pain referred to the ear, supraorbital or occipital areas is common. *Extension to the base of the skull may produce involvement of cranial nerves, most often of the sixth, ninth, tenth, eleventh or twelfth.* Metastases, eustachian tube obstruction, middle ear infection or cranial nerve involvement may produce the symptom leading to discovery of the primary lesion. The nasopharyngeal tumor may be so small as to escape detection unless the examination is exceedingly thorough. A remnant of adenoid tissue often persists in the adult as a mass in the midline of the vault of the nasopharynx. Biopsy will differentiate it from a malignant lesion.

The treatment of malignant neoplasms of the nasopharynx, whether carcinoma or sarcoma, is irradiation. Surgery, other than for biopsy, should not be attempted. One of the contraindications to surgical treatment of malignant tumors of the nose and sinuses is involvement of the nasopharynx and this applies equally when the growth is primary in the area.

The Ears

By THEODORE E. WALSH, M.D.

THEODORE EDWIN WALSH was born in Calcutta and educated at King's College, Cambridge University. He served as a medical officer in Borneo and came to the United States in 1929 when he joined the faculty of the University of Chicago. After nine years, he became the Professor and Chairman of the Department of Otolaryngology at Washington University, the chair he now occupies. His many contributions in his field of surgery have received laudatory recognition.

ACUTE OTITIS MEDIA

Acute otitis media is an acute inflammation of the mucosa of the middle ear space. It is the result of a direct spread of infection from the nasopharynx via the eustachian tube and is secondary to acute infection of the upper respiratory tract.

The pathologic changes observed in the ear vary with the severity of the infection and the virulence of the invading micro-organism. In mild infections, there is edema of the mucosa with an intact epithelium. The swelling of the mucosa may lead to blockage of the eustachian tube and some exudation of fluid into the middle ear. The fluid is mucoid and contains few cells.

When the infection is severe, marked edema of the mucosa with necrosis of the epithelium occurs. The tympanic membrane becomes swollen, thickened and necrotic, leading to perforation. There is considerable exudation of fluid containing many cells. In the more severe infections, direct spread through the aditus ad antrum leads to infection of the mastoid air cells, i.e., *acute mastoiditis*. The continuity of the mucosa of the middle ear and of the mastoid antrum and air cells makes the concept tenable that in any instance of acute otitis media there is some degree of mastoiditis.

Pain, of sudden onset, referred to the ear and spreading to the parietal and occipital areas, is the most common symptom. The pain may be steady or lancinating and severe. It increases in intensity until the drum ruptures or until paracentesis relieves the pressure of the fluid in the middle ear.

In the more severe infections, when the mastoid is involved, tenderness is present

behind the ear and is most common over the region of the mastoid antrum, on the tip of the mastoid process and over the area of the emissary vein.

Swelling behind the ear may occur and is due to inflammation of the postauricular lymph nodes or to edema of the soft tissues. When acute mastoiditis is present and breakdown of the bone occurs, subperiosteal accumulations of pus may result.

Elevation of temperature is usual in all of the more severe infections. A fever may range from 38° to 41° C. It may be accompanied by chills.

Hearing loss is present early and the loss is of a conductive type. It is usually not severe and a threshold loss of approximately 10 to 30 decibels is common.

The ear drum shows progressive signs of inflammation. Early, dilatation of vessels is noted especially at the periphery of the pars tensa and along the handle of the malleus. As fluid accumulates in the middle ear, bulging of the posterior half of the drum occurs and the normal landmarks become less easily recognized. Later, there is complete bulging and reddening of the drum. When perforation occurs spontaneously, it is usually in the anterior inferior quadrant.

At the onset of pain and loss of hearing, appropriate antibiotic and/or sulfonamide therapy should be instituted. Until the infecting organism can be identified, broad spectrum drugs are advisable and should be administered in adequate dosage. If there is any evidence of fullness in the drum, early myringotomy is indicated. Since the advent of the antibiotics and sulfonamides, the tendency has been to refrain from myrin-

gotomy. The physician has been lulled into a sense of security by the clinical response of the patient to the antibiotics, e.g., by resolution of the temperature, remission of pain and other symptoms. The failure to provide adequate drainage to fluid entrapped in the middle ear leads to increasing permanent loss of hearing and to recurrent otitis media and mastoiditis.

In the presence of inflammation of the drum, myringotomy must be performed with the patient under anesthesia. For small children, a general anesthetic is to be preferred, for adults, a local anesthetic may be adequate, provided it is carefully administered. The anesthetic of choice is Bonan's solution, but it must be used with care. A small cotton wick with only a small portion of the tip moistened with the solution is placed against the ear drum at a point chosen for myringotomy. Care must be taken to avoid contact of the solution with the skin of the external auditory canal. A crescentic incision in the lower quadrant of the drum is made with a sharp-pointed knife. Local application of boric acid and alcohol and frequent cleansing with sterile cotton-tipped applicators under direct vision will usually lead to healing. Resolution of the infection occurs in from one to four weeks. In the event that the mastoid has been involved in the infection, healing may occur with adequate antibiotic therapy. In the process of healing, the fluid in the air spaces of the mastoid process becomes organized by an ingrowth of fibrous connective tissue from the mucosa lining and fibrous tissue is formed in an air space. Osteoblasts lay down new lamellar bone and the air space becomes converted into fibrous tissue and new bone with very small, air-containing cavities. In the event that the infection is not overcome by the antibiotics, decalcification of the bony trabeculae occurs and an abscess forms in the mastoid. This necessitates surgical drainage.

Signs pointing to the necessity for surgical intervention in mastoiditis are:

1. Persistent discharge from the middle ear for more than four to six weeks after adequate antibiotic therapy.
2. Persistent tenderness over the mastoid area in spite of adequate antibiotic therapy.
3. Sagging of the posterosuperior external auditory canal wall indicating bony breakdown in the air cells around the antrum.
4. Persistent elevation of temperature.
5. Evidence of spread of infection to adjacent structures, such as the lateral sinus and the meninges. Confirmatory evidence

of bony breakdown may be obtained from roentgenograms of the mastoids.

The operation for acute mastoiditis is designed to promote drainage and to excise diseased tissues. The incision of choice is a postauricular one which is made through the skin, superficial tissues and periosteum to the bone. The periosteum is reflected and the cortex exposed. The cortex is entered with a round cutting burr. The mastoid air cells are thoroughly exenterated and the short process of the incus lying in the aditus ad antrum is visualized, the aditus being slightly enlarged to permit free drainage from the middle ear. After all the cells have been carefully exenterated and the landmarks clearly visualized, the incision is closed in layers, care being taken to approximate the periosteum. A drain is left in the lower end of the wound for a few days.

SEROUS OTITIS MEDIA

Serous otitis media is the result of obstruction of the eustachian tube leading to improper ventilation of the middle ear. This may occur as a result of an acute respiratory infection or from obstruction due to allergy. It may occur in sudden descents in an airplane when the eustachian tube does not open adequately (aero-otitis). Eustachian tube obstruction may occur in association with tumors in and about the region of the pharyngeal orifice of the tube. This should be always borne in mind. The symptoms and signs of serous otitis are: a sudden loss of hearing in the affected ear, a sensation of fullness, tinnitus which is described frequently as a roaring sound or as a pulsating sound in the ear and is extremely annoying, and autophony—the patient states that when he speaks his voice sounds to him "as though his head were in a barrel." Examination of the ear reveals a peculiarly clear-appearing drum. The drum is slightly retracted, in those subjects in whom the middle ear is not completely full of fluid, a fluid level may be seen both in the posterior and anterior parts of the drum. In those patients in whom the middle ear is completely full of fluid, there is a characteristic appearance of the drum in which the short process and the handle of the malleus are peculiarly prominent and seem to be a clear white. The rest of the pars tensa has a distinct lemon-yellow color and the drum appears transparent. It is not unusual to be able to see, through such a drum, structures in the middle ear, the niche of the round window, the long process of the incus and

The Ears

By THEODORE E. WALSH, M.D.

THEODORE EDWIN WALSH was born in Calcutta and educated at King's College, Cambridge University. He served as a medical officer in Borneo and came to the United States in 1929 when he joined the faculty of the University of Chicago. After nine years, he became the Professor and Chairman of the Department of Otolaryngology at Washington University, the chair he now occupies. His many contributions in his field of surgery have received laudatory recognition.

ACUTE OTITIS MEDIA

Acute otitis media is an acute inflammation of the mucosa of the middle ear space. It is the result of a direct spread of infection from the nasopharynx via the eustachian tube and is secondary to acute infection of the upper respiratory tract.

The pathologic changes observed in the ear vary with the severity of the infection and the virulence of the invading micro-organism. In mild infections, there is edema of the mucosa with an intact epithelium. The swelling of the mucosa may lead to blockage of the eustachian tube and some exudation of fluid into the middle ear. The fluid is mucoid and contains few cells.

When the infection is severe, marked edema of the mucosa with necrosis of the epithelium occurs. The tympanic membrane becomes swollen, thickened and necrotic, leading to perforation. There is considerable exudation of fluid containing many cells. In the more severe infections, direct spread through the aditus ad antrum leads to infection of the mastoid air cells, i.e., *acute mastoiditis*. The continuity of the mucosa of the middle ear and of the mastoid antrum and air cells makes the concept tenable that in any instance of acute otitis media there is some degree of mastoiditis.

Pain, of sudden onset, referred to the ear and spreading to the parietal and occipital areas, is the most common symptom. The pain may be steady or lancinating and severe. It increases in intensity until the drum ruptures or until paracentesis relieves the pressure of the fluid in the middle ear.

In the more severe infections, when the mastoid is involved, tenderness is present

behind the ear and is most common over the region of the mastoid antrum, on the tip of the mastoid process and over the area of the emissary vein.

Swelling behind the ear may occur and is due to inflammation of the postauricular lymph nodes or to edema of the soft tissues. When acute mastoiditis is present and breakdown of the bone occurs, subperiosteal accumulations of pus may result.

Elevation of temperature is usual in all of the more severe infections. A fever may range from 38° to 41° C. It may be accompanied by chills.

Hearing loss is present early and the loss is of a conductive type. It is usually not severe and a threshold loss of approximately 10 to 30 decibels is common.

The ear drum shows progressive signs of inflammation. Early, dilatation of vessels is noted especially at the periphery of the pars tensa and along the handle of the malleus. As fluid accumulates in the middle ear, bulging of the posterior half of the drum occurs and the normal landmarks become less easily recognized. Later, there is complete bulging and reddening of the drum. When perforation occurs spontaneously, it is usually in the anterior inferior quadrant.

At the onset of pain and loss of hearing, appropriate antibiotic and/or sulfonamide therapy should be instituted. Until the infecting organism can be identified, broad spectrum drugs are advisable and should be administered in adequate dosage. If there is any evidence of fullness in the drum, early myringotomy is indicated. Since the advent of the antibiotics and sulfonamides, the tendency has been to refrain from myrin-

ized into fibrous tissue and a true adhesive deafness follows. In these subjects, we have seen strands of fibrous tissue binding down the ossicular chain and giving rise to a conductive deafness resembling that of otosclerosis. Rarely, in patients in whom there is a considerable accumulation of mucus in the middle ear with blockage of both of the round window and immobilization of the ossicular chain, hearing loss will be profound with all the characteristics of perceptively deafness.

CHRONIC OTITIS MEDIA

Chronic otitis media is the result of unresolved acute otitis media. The patient complains of a chronically discharging ear with some loss of hearing acuity. This disease may be classified into three types.

Type I is characterized by an intermittent or constant discharge from the ear which is frequently scanty and becomes more profuse when a respiratory infection is present. The discharge is mucoid and, under ordinary conditions of cleanliness, without odor. The discharge may cease spontaneously only to recur with the next respiratory infection. On examination of the ear, there is seen a perforation usually in the anteroinferior quadrant which may be small. The hearing in such subjects is not remarkably depressed, commonly from 10 to 30 decibels of conductive loss being found. The discharge from the ear is due to a low grade infection of the mucosa of the middle ear and of the eustachian tube with secretion of mucus from the goblet cells in the eustachian tube and in the mucosa of the middle ear.

Type I chronic otitis media is a condition which is not dangerous to life. Surgery should be aimed at restoration of function rather than excision of disease. Of paramount importance is attention to the nasopharynx with the object to eliminate any chronic upper respiratory infection either in the nasopharynx or in the sinuses and also to prevent recurrent acute infections.

If the ear canal is wide enough to permit adequate operating space, the perforation in the drum can frequently be healed by myringoplasty.

In this operation, the superficial layer of epithelium from the drum is removed and the edge of the perforation freshened. The epithelium is removed for approximately 5 mm. all around the perforation. Then a thick split-thickness graft is taken from some area of skin that is not hair bearing and the

packed in with cotton balls. This should be left without interference for ten days. The objective of closing the perforation is to rehabilitate the patient so that he may get water in the ear with impunity, may go swimming, etc. The operation also will often improve the hearing to within normal limits, provided there is no actual fixation of the ossicular chain.

Local therapy to the ear consists of cleanliness for which applications of boric acid and alcohol are used.

The patient with type II chronic otitis media complains of a constant, foul-smelling discharge from the ear. This discharge may be profuse, is constant and in spite of all efforts of cleanliness is malodorous. Examination of the ear shows a large perforation frequently occupying most of the pars tensa. The handle of the malleus may be retracted and appear foreshortened. The medial wall of the tympanum may be covered with granulations or one may see polyps filling the external auditory canal. The perforation of the drum is central and does not involve the annulus or margin of the drum. The pathologic process in this instance is one of a low grade osteitis of the ossicular chain or of the bony trabeculae in the epitympanum and hypotympanum and of the pentabul air cells. The hearing is usually markedly depressed and commonly 40 to 50 decibels threshold loss for the pure tones is found. The bone conduction in most instances is good, but if the disease is present for a long time more and more nerve involvement may occur so that bone conduction is depressed. Because of the inaccessibility of the disease process to medication, local treatments to the middle ear are, as a rule, ineffective. In some subjects, it is possible to displace antibiotic solutions into the middle ear and effect remission of the disease. As a rule, however, cure can only be effected by radical mastoidectomy.

Type III chronic otitis media is a condition which is potentially dangerous to life. The discharge may be intermittent and on occasions scanty. The hearing is usually good, a threshold loss of less than 15 decibels is not uncommon. The perforation, which is marginal involving the annulus, is usually seen in the posterosuperior quadrant of the drum, through the pars flaccida or sometimes extending to the anterosuperior portion of the drum. On occasions, the perforation is so small that it is difficult to visualize without adequate magnification; sometimes it may be covered with a small

the incudostapedial joint, and the tendon of the stapedius muscle.

Treatment consists of evacuation of the fluid from the middle ear by paracentesis. For this no anesthetic is required. It is preferable not to prepare the external auditory canal by any cleansing. If wax and debris obstruct a clear view of the drum, they can be gently removed with cotton-tipped applicators, but application of antiseptics or cleansing agents in the canal should be avoided. An adequate speculum and good illumination are essential and with a very sharp paracentesis knife a small puncture is made in the inferior portion of the pars tensa. By the use of a pneumatic otoscope, fluid may be aspirated from such a perforation or, with the use of a small suction tip, the ear may be evacuated. It is essential at this time that the eustachian tube be inflated to insure complete evacuation of fluid from the middle ear. After such a procedure, the hearing is returned to normal almost immediately. In most cases, the perforation heals by the day following treatment and the condition is cured.

When there is a persistent recurrence of fluid in the middle ear, further etiologic factors must be sought. In many of these patients allergy is the cause. It should be repeated that in the presence of serous otitis the greatest attention should be paid to the nasopharynx to eliminate all possibilities of tumor. It is not infrequent that serous otitis is the only early evidence of malignant disease in the nasopharynx.

Examination of the ear requires the use of a pneumatic otoscope and with this instrument it is seen that in serous otitis the ear drum will not move normally. There seems to be always a "splinting" of the drum when fluid occupies the middle ear space. Evacuation of fluid from the middle ear may be accomplished on occasions by eustachian tube inflation alone. If the patient is placed in such a position that the affected ear is upward and gentle inflation done by Politzer's method, fluid may be evacuated from the ear as air replaces it. This method, however, does not always completely evacuate the fluid and paracentesis is the preferable treatment. In some instances, fluid re-forms in the middle ear in spite of paracentesis and in spite of all efforts at medical therapy to control allergic and other factors. In such subjects a simple mastoidectomy has been recommended. We do not recommend mastoidectomy for these patients as it has been our experience that, in spite of all the mas-

toid cells being removed, fluid still accumulates in the middle ear from the middle ear mucosa. In patients with chronic disease in whom fluid reaccumulates in the ear, the insertion of a small polyethylene tube through the pars tensa into the inferior portion of the middle ear is recommended and has been found successful in many instances. This tube may be left in place for a week or ten days and, when the ear is dry, the tube is removed and the perforation closes spontaneously.

CHRONIC MUCOUS OTITIS MEDIA

Chronic mucous otitis media is the result of a low grade infection in the middle ear or is due to the improper treatment of acute otitis media of low virulence. Nowadays, more and more cases of chronic mucous otitis are observed in children who have had acute otitis media treated with antibiotics without the benefit of myringotomy. The common complaint is difficulty in hearing. The deafness is found to be of a conductive type. In mucous otitis the drum is thickened, dull and has a peculiar creamy appearance. With magnification and with the use of a pneumatic otoscope, the posterior half of the drum is seen to be slightly full and does not move adequately on positive or negative pressure. The landmarks are visible but are slightly distorted by the thickened appearance of the drum and its immobility. The treatment is wide myringotomy and this must be done with the patient under general anesthesia. It is not possible adequately to evacuate the middle ear of mucus with the patient under local anesthesia because frequently such evacuation necessitates the use of very strong suction and sometimes of forceps. Any trauma to the promontory causes considerable pain. We have found it necessary on many occasions to make two incisions, one in the lower part of the drum and a counterincision high anteriorly to allow for the entrance of air as the mucus was being evacuated. This mucus is tenacious, sticky and sometimes is extremely difficult to remove. Inflation of the eustachian tube after myringotomy and careful attention to the nasopharynx are important. It is fortunate that in most patients in whom mucus has been evacuated from the middle ear, it will not re-form and the patient's hearing is restored. Occasionally, with subsequent mild respiratory infections, further accumulation of mucus may occur. In the event that no treatment is provided, it is not infrequent for such mucus in the ear to become organ-

unusual that there will be an intact ossicular chain, so generally the incus and malleus must be removed. This is accomplished while preserving the tympanomeatal skin flap and any of the pars tensa possible. Diseased mucosa is removed from the promontory, but the eustachian tube is not curetted. Perforations in the pars tensa are closed by a tympanomeatal flap or by a thin full-thickness skin graft. The tympanomeatal flap or skin graft is packed down onto the head of the stapes. An attempt is made to create an air-containing space between the eustachian tube and the round window. This is usually possible by the use of a small amount of Gel-foam in the hypotympanum which, when absorbed, leaves an air space. When such an air space can be obtained and good contact is made between the skin graft and the head of the stapes, hearing is remarkably restored.

DEAFNESS

Deafness may be conductive or perceptive. Conductive deafness results from interference with sound impulses reaching the inner ear by occlusion of the external auditory canal, by wax, foreign bodies, inflammation or tumors, by disease of the middle ear structures as in otitis media, either acute or chronic, in which the continuity of the ossicular chain is broken or in which adhesions may form in the middle ear, by fixation of the ossicular chain as in otosclerosis. When sound impulses reach the inner ear but are not perceived or correctly interpreted, there is perceptive deafness. This may be due to a lesion in the end organ in the cochlea or to lesions in the cochlear division of the eighth nerve or in the central cerebral pathways.

Tests of hearing are performed with tuning forks and audiometers. Fork tests are qualitative tests and they compare the patient's ability to hear by bone and air conduction.

The Rinne test compares the patient's hearing by bone and air conduction. Normally, when a tuning fork is struck and the stem held on the mastoid process, the sound can be heard in the homolateral ear for a certain number of seconds. After it has ceased to be heard behind the ear, and the tines of the forks then are held close to the external auditory canal, the sound is again perceived. This is termed a "positive Rinne." In perceptive deafness the Rinne is positive; in other words, the patient will hear longer by air conduction than by bone conduc-

tion. In conductive deafness, the contrary is true and the patient will hear better by bone conduction than he will by air conduction. This is termed a "negative Rinne."

The Weber test compares the ability of the two ears to hear by bone conduction. The tuning fork is struck and the stem held on the vertex of the head or on the upper incisor teeth. When the hearing is unequal in the two ears, the sound will be referred to the better ear in perceptive deafness and to the worse ear in conductive deafness.

The Schwabach test compares the ability of the patient to hear by bone conduction with that of the observer. The tuning fork is struck and held on the observer's mastoid process until he can no longer hear it and then on the patient's mastoid process and vice versa. In perceptive deafness, assuming that the observer's hearing is normal, the patient will not hear as well by bone conduction as will the observer. On the other hand, assuming that the observer's hearing is normal, in conductive deafness the patient will hear for a longer period than the observer. Fork tests, therefore, are qualitative tests of the hearing and differentiate between perceptive and conductive deafness.

Audiograms measure the patient's threshold of hearing and are plotted in relation to the established normal. Audiograms are made either with pure tones, usually at octave intervals from 128 double vibrations up to 8192 double vibrations, or the signal instead of pure tones may be speech. A pure tone audiogram measures only the patient's threshold of hearing for pure tones. Speech audiograms measure not only the threshold of hearing for speech, but the ability of the patient to understand speech when the signal is given at an intensity easily heard by the patient. Therefore, it measures not only the threshold but the suprathreshold areas of hearing for speech. The importance of speech testing cannot be overestimated in relation to rehabilitation of patients for everyday life. To translate pure tone losses into losses for speech is not justifiable.

Perceptive deafness may be congenital or acquired. In the *congenital* type the parents usually notice that their child is deaf because he may not develop speech at the normal time or he may not respond adequately to sounds. To dismiss parents of such a child with the remark, "there is nothing to be done," is inexcusable. These parents need encouragement from physicians and they should be told that, although there is no medical treatment which can restore

dry crust which may be mistaken for cerumen. In almost every instance, a history of previous ear infection in childhood can be obtained and on careful examination it will be seen that through the perforation one can obtain flakes of desquamated epithelium and sometimes pus. If pus is present, it invariably has an extremely unpleasant foul odor. Occasionally there are granulations and almost always cholesteatosis. Cholesteatosis occurs when there is metaplasia of the squamous epithelium through a marginal perforation of the drum and a continued growth of such epithelium into the epitympanic space, mastoid antrum and middle ear. In the presence of an acute exacerbation in such an ear, intracranial complications are frequent and may occur with distressing suddenness. It has been thought that the absorption of bone which accompanies cholesteatosis is due to pressure of desquamating epithelial cells which are unable to be extruded through the small perforation. However, on examination of the sections of ossicles removed at operation in patients with cholesteatosis, it is seen that the subepithelial connective tissue matrix extends along the haversian canals through the periosteal layer of bone to come to lie adjacent to calcified cartilaginous rests in the enchondral layer. In many instances, these are seen to be undergoing decalcification, possibly from chemical lysis. In these patients an acute superimposed infection may extend through the bone and give rise to labyrinthitis, epidural abscess or lateral sinus thrombosis. In many instances, acute infection superimposed on chronic type III otitis may lead to brain abscess presumably by retrograde thrombosis of the vessels in the vicinity. Surgery in the type III ear is aimed at excision of disease and preservation of function. This is usually accomplished by a radical mastoidectomy.

In any patient with chronic otitis media, if there is superimposed an acute infection, complications are possible. They are lateral sinus thrombosis and perisinus abscess, meningitis, labyrinthitis and brain abscess.

Pain in the ear and headache, referred to the temporal and occipital areas of the affected side, are indications that infection is extending beyond the ear. Spiking temperature, with or without chills, is an indication of lateral sinus involvement. A lack of rise in the cerebrospinal fluid pressure with compression of the jugular vein indicates the probability of lateral sinus thrombosis. Stiff neck, an increased cerebrospinal fluid pres-

sure and the presence of cells in the cerebrospinal fluid are indicative of meningitis. Attacks of vertigo with the production of nystagmus, or the ability to produce nystagmus on positive or negative pressure in the ear, indicate a labyrinthine fistula.

The surgical treatment of chronic otitis media is aimed at excision of diseased tissue with preservation of function wherever possible.

Tympanoplasty. In those cases of chronic otitis media in which there is a large perforation of the pars tensa, but in which discharge is absent and no active infection is present, the hearing may be improved and the ear made safer by closure of the perforation by a skin graft. A very thin full-thickness graft is taken from behind the ear. Through a large ear speculum under magnification, the edges of the perforation are freshened and the epithelium removed from the drum and from the skin of the canal for approximately 0.5 cm. from the edge of the perforation. The graft is now placed against the freshened area and held in with appropriate packing for approximately ten days. The patient is cautioned against nose blowing. Such grafts take in a high percentage of cases and, with closure of the perforation, hearing is improved and the likelihood of subsequent acute exacerbations is lessened.

Radical Mastoidectomy. This procedure is performed in those cases of chronic otitis media in which the hearing is so far deteriorated that any restoration is impossible. The endaural approach is preferable as it affords the most direct route to the disease. All diseased cells in the mastoid are exterminated. The bridge over the aditus ad antrum is thinned and removed. The outer attic wall is removed and the epitympanum is exposed. The incus and malleus are removed and the hypotympanic area thoroughly exposed by lowering the facial ridge. The tensor tympani muscle is removed and the eustachian tube and peritubal cells are curetted. All mucosa is removed from the middle ear. The eustachian tube is plugged, preferably with bone taken from the superior iliac crest. A full-thickness graft taken from behind the ear is placed in the middle ear and held in with proper packing.

Modified Radical Mastoidectomy. In those cases of chronic otitis media in which there is little demonstrable perceptible loss of hearing, every effort should be made to restore the conductive loss. The objective of surgery should be to eliminate the disease with preservation of any normal tissue. It is

When this is successfully accomplished, there is an immediate improvement in hearing which can be demonstrated by audiometry in the operating room. Success with this operation is at present possible in only approximately 50 per cent of attempts. Following mobilization of the stapes, the tympanomeatal flap is replaced. No packing is necessary in the ear and healing is rapid.

Fenestration Operation. An endaural incision is made and sufficient mastoid cells everted to make possible the approach to the horizontal canal and its anterior end. The incus and head and neck of the malleus are removed after the tympanomeatal flap has been mobilized and cut. The flap is thoroughly cleansed of any bone chips and, under high magnification, the fenestra is made anteriorly in the amputated end of the horizontal canal. The fenestra usually is approximately 3 to 4 mm. in length by 1 to 1.5 mm. in width. When this has been cleanly accomplished, the tympanomeatal flap is placed firmly against the fenestra and held in place with packing. The results from fenestration have been successful in about 85 to 90 per cent of ideal cases and hearing has been maintained for periods up to fourteen years.

In comparing the two surgical procedures, it is evident that stapes mobilization is less immediately traumatic to the patient and causes less postoperative morbidity. The chance of success in restoration of hearing, however, is infinitely greater with fenestration.

MENIERE'S DISEASE

Meniere's disease is characterized by nerve deafness, tinnitus and vertigo.

The pathologic process in this disease is that of increased endolymphatic pressure in the scala media. Sections of temporal bones from patients with Meniere's disease, who have died from other causes, have shown dilatation of the cochlear duct and herniation of the utricle and saccule into the amputated end of the semicircular canals.

Meniere's disease (endolymphatic hydrops) is primarily a cochlear disease. A careful history will reveal that the disturbance of hearing has been present usually a long time before the disabling symptom of vertigo appears. The patient usually presents himself complaining of vertiginous attacks with accompanying tinnitus; the history of deafness has to be elicited.

There is a true aural vertigo. The patient states that the vertigo may come on sud-

denly at any time. Frequently, it will occur when he is in bed. There is a sensation of objects moving in a rotary fashion or sometimes the patient complains that he himself seems to be spinning. The vertigo is usually accompanied by nausea and vomiting and is incapacitating. It may last for a few minutes or for several days. The attacks may occur fairly regularly at biweekly or monthly intervals or occur frequently and at irregular intervals. There may be long periods of freedom from attacks.

The tinnitus is usually a roaring sound likened by some to the sound heard on holding a sea shell to the ear. It may be described as "the sound of surf on the seashore," or "of a wind in the forest." Or, there may be an intermittent and much less bothersome high-pitched ringing. In many instances the tinnitus either disappears just preceding a vertiginous attack or may become very much louder temporarily and be followed by the vertiginous attack.

The patient notices a loss of hearing in the affected ear. He usually can state that although he hears sounds, the sounds are distorted and they sound different in the two ears (diplacusis). Although speech can be heard, it frequently cannot be understood. The hearing varies considerably and patients will state that at times they hear "perfectly," while at other times there is a "sense of pressure or fullness" in the ear and the hearing ability is impaired. Those patients who are musical complain bitterly of the difference in pitch appreciated by the two ears. Many patients state that loud sounds hurt the affected ear.

Usually the examination of the ear, nose and throat is unrevealing, but the functional tests will show abnormalities.

Fork tests as a rule give characteristic findings of nerve deafness. The Rinne test is positive. In the Weber test the sound is referred to the better ear. In the Schwabach test the bone conduction is diminished. Comparison of the sounds made by a tuning fork held close to each ear alternately reveals that the same fork may sound higher or lower in the affected ear than in the normal one. The sound, too, is not clear but is described as "fuzzy." Diplacusis may be present only in the low tones or only in the high, or may be confined to only one frequency, but it is nearly always present. This diplacusis can be measured.

The pure tone audiogram reveals a threshold loss of hearing more marked in the low tones in the earlier stages, later becoming a

the congenitally deaf patient's hearing, he may be taught to speak and be able to go through his educational years provided the training is started early. It is suggested that the parents apply at special schools for the deaf and that the child should start his education when three years of age.

Acquired deafness may be caused by toxic factors or agents. Examples are such drugs as quinine and streptomycin or various virus infections such as mumps, measles and influenza. In toxic deafness, the hearing loss is commonly about the same throughout the scale, low tones being affected as much as high tones. There is frequently an accompanying tinnitus which is extremely bothersome. The speech audiogram will show a threshold loss of hearing varying in degree, but the discrimination ability of the patient is markedly depressed. He will understand probably less than 40 per cent of the words which he hears. It is important to realize that acquired toxic nerve deafness is not amenable to therapy and the patient should be encouraged to learn "to hear with his eyes and with his brain" rather than with the ears and should be discouraged from continual therapy with vitamins and other nostrums so commonly advised.

Presbycusis occurs in persons of advancing age and is characterized by a loss in the high tones. The threshold of hearing for speech is not greatly impaired as the hearing for 500 and 1000 cycle tones is commonly good. The ability to understand speech is impaired, i.e., there is a marked discrimination loss.

The term *casomotor deafness* may be used to describe such conditions as Meniere's disease, in which the hearing loss fluctuates from time to time and may be accompanied by tinnitus and dizziness. In early cases it is possible sometimes to arrest the hearing loss by use of vasodilator drugs.

Conductive deafness is the only form of deafness which can be helped surgically. Wax and foreign bodies in the external auditory canal should be removed with care. In most subjects, syringing with warm water is the method of choice for removal. If instrumentation is necessary, the utmost care should be taken not to push the foreign body further into the canal or through the drum into the middle ear. If difficulty is encountered in the removal of a foreign body, a general anesthetic should be used. Deafness due to accumulation of fluid in the middle ear can be promptly relieved with myringotomy.

Adhesive deafness can be greatly helped by adequate surgery to the middle ear and/or by fenestration.

Otosclerosis is a disease of youth. It is between four and eight times more common in women than in men. The deafness is commonly first noticed when the subject is in the late teens or early twenties and is progressive. Patients with otosclerosis complain of tinnitus, of being unable to hear unless people speak loudly but of being able to hear perfectly when the sound is made loud enough. They hear better in a noisy place than in a quiet one and usually well over the telephone. The patients themselves have a soft, quiet, well modulated voice and good articulation. Examination shows the ear, nose and throat to be entirely normal except that, not infrequently, the tympanic membrane is seen to be atrophic and there may be patches of atrophy resembling healed perforations. In some subjects in whom the disease is active, there may be seen a pink glow through the drum which is the result of vasodilatation in the mucosa over the promontory (Schwartz's sign). Hearing tests in persons with otosclerosis demonstrate a negative Rinne, an increased Schwabach and in the Weber test the sound is referred to the ear with the greater hearing loss. With pure tones there is a threshold loss for air-conducted sounds, but there is normal, or near-normal, bone conduction.

Speech tests show a threshold loss comparable to that of the pure tones and the patient can repeat correctly ± 100 per cent of the words heard if they are given loudly enough (normal discrimination).

Patients with otosclerosis may be helped by mobilization of the stapes or by fenestration.

Stapes Mobilization. The operation for mobilization of the stapes is done under local anesthesia through a large ear speculum. An incision is made approximately 5 mm from the annulus tympanicus from eleven o'clock to six o'clock on the right side and from one o'clock to six o'clock on the left side and the skin is elevated from the bony canal wall. The drum is lifted out of the annulus and turned forward so that the middle ear is exposed. Further exposure must be obtained by removal of the thin margin of bone of the posterior canal wall until a good view of the incudostapedial joint and the foot plate of the stapes is obtained. With pressure on either the incus or on the margins of the foot plate, an attempt is made to mobilize the fixed stapedial foot plate.

underside of the facial nerve, or, possibly, might be caused by heat if the area is not satisfactorily dried before the current is applied, in effect boiling the undersurface of the nerve. In any event, if the patient does by misfortune show a facial paralysis following the operation no time should be lost before the nerve is completely decompressed.

Labyrinthotomy is simpler and preferable to section of the eighth nerve. Differential section has no place in the treatment because the hearing is impaired and its preservation is not worth while.

TUMORS

Benign tumors of the middle ear and external ear are commonly the result of supuration in the ear. Fibromas or fibrous granulations and polyps may be seen in the external ear coming through a perforation in the drum.

Osteomas occur in the external bony canal. They seldom give rise to symptoms unless they increase in size sufficiently to occlude the canal and cause deafness. These tumors are small, usually present on the superior and posterior aspects of the external auditory canal, and can be removed easily by elevation of the skin in the canal and removal of the mass by cutting burs or curets.

Chemodectomas may arise in the middle ear and may present in the external canal either through a perforation of the drum or they may be present with an intact drum. They are not common tumors.

Carcinoma of the middle ear is rare and the prognosis is poor. Carcinoma of the external canal may occur and invade the middle ear space. If such a tumor is found early and is removed by an extremely radical excision, the prognosis is fair, but recurrence locally is common. An extension intracranially is usually the cause of death. The results of x-ray therapy of squamous carcinoma of the middle ear are disappointing.

Sarcoma of the external ear with extension to the middle ear is rare but does occur occasionally in children.

MALFORMATIONS

Congenital agenesis of part of the ear may occur. Microtia, with partial or complete atresia of the external auditory canal, with or without agenesis of the middle ear, may be present. It may be unilateral or bilateral. In unilateral cases, it is usually unnecessary to reconstruct a middle ear as the hearing with one normal ear is not a sufficient handi-

cap to warrant surgery. Plastic reconstruction of the external ear is advisable, particularly in boys, for cosmetic reasons. In the bilateral cases, it is important to determine early whether there is hearing by bone conduction and, if so, it is possible to reconstruct the middle ear and improve function and at a later date still further improve hearing by fenestration. The operation for restoring the middle ear function is difficult because the landmarks are distorted. The cortex of the bone is removed and the middle ear space found. Usually, the external auditory canal is represented by fibrous tissue and the drum is represented by a bony plate. Frequently the middle ear space is normal, except that usually the incus and malleus are distorted, fused and in an abnormal position. They are removed. The bony plate representing the drum is removed to an extent which allows for entrance to the middle ear. A skin graft is placed over the defect so caused and attached to the horizontal canal, thus forming a closed tympanic space. The meatus may be kept open with skin grafting and with packing. If one is successful in re-forming an external auditory canal and middle ear, plastic reconstruction of the external ear may be done at a later date. Reconstruction of the middle ear should be done when the child is from three to five years of age to avoid poor speech habits which result from deafness.

flat loss throughout the scale and still later showing a greater loss for the high frequencies. The bone and air thresholds are equal. Loudness balance tests reveal recruitment or hyper-recruitment.

Speech audiometry characteristically shows a proportionally greater loss for discrimination than might be expected from the threshold loss. We have found in our patients that whereas the loss at threshold for speech is perhaps only 40 decibels, the discrimination score is frequently less than 30 per cent.

Caloric tests are not diagnostic in Meniere's disease. In the early stages, one may find that the responses in the affected ear are equal to those of the normal ear. Later, as a rule, the affected ear becomes hypoactive and one may find a directional preponderance to the unaffected side. In patients with long-standing cases, one may obtain no response to stimulation of the affected ear even with maximum stimulation with ice water.

Although the cause of Meniere's disease is not known, clinical evidence is accumulating which points to the possibility of a vasomotor change leading to spasm of the internal auditory artery. Such vasomotor change may be the result of an allergic state, for example, a true hypersensitivity to foods or inhalants. Endocrine imbalances or psychogenic stimuli may have an effect. It is of importance to investigate all possibilities and eliminate the possible causative factors. However, such investigation is difficult and frequently time consuming and treatment should be instituted early. If the theory of a vasospastic state is correct, it is important to relieve this spasm and vasodilators have been recommended. The use of Ronacol or nicotinic acid (50 mg.) together with thiamine chloride (10 mg.) and ascorbic acid (250 mg.), three times a day with meals, is often helpful. In addition, Bantline (50 mg.), or Pro-Bantline (15 mg.), is given every six hours. In some cases, atropine (1/50 grains three times a day by mouth) has proved beneficial. In many subjects, this has prevented the dizzy spells, although others under such therapy have had attacks.

In a few of the patients, large doses of vitamin B₁₂ have been used with apparent success. One thousand micrograms are given intramuscularly daily for thirty days, and thereafter as a maintenance dose at intervals to be determined. Although the patients who have benefited from this treatment are few, it perhaps warrants further trial.

Histamine therapy has proved valuable in some instances. The patient is tested with an intradermal injection of histamine at dilutions of 1:100,000,000, 1:10,000,000; 1:1,000,000 and 1:100,000. If he shows a definite reaction—a wheal with or without erythema—the dilution with which the least positive reaction was obtained is used. Biweekly doses are given starting with 0.1 cc. and increasing by 0.1 cc. each time until there is response. Thereafter, weekly injections of the appropriate dose are given. By this means, a reversal of the hearing loss and a disappearance of symptoms have been obtained in a number of patients. It should be noted that if too large a dose is given, the hearing again becomes worse and the tinnitus and vertigo reappear.

Normal remissions in this disease make it difficult to evaluate therapy and one must be guarded in ascribing to therapy what may be the result of a normal fluctuation in the disease.

When the patient has not been helped with medical management and has become incapacitated or handicapped by his disabling vertigo, destruction of the labyrinth will give complete relief from the symptoms provided only one ear is diseased. It is emphasized that labyrinthotomy is reserved for patients in whom the disease is unilateral.

Labyrinthotomy is a simple procedure performed either through an endaural or a postauricular approach as the surgeon desires. Enough mastoid cells are excised to allow for a direct approach to the horizontal semicircular canal and, particularly, to its anterior end. It is usually advantageous to remove the mecus and the head of the malleus to have an easier access to the vestibule. A large opening is made in the vestibule. The endolymphatic labyrinth is avulsed and, after the area is carefully dried, a coagulating current is applied to the vestibule in order to destroy both utricle and saccule completely.

Results from labyrinthotomy are universally good if an adequate destruction is accomplished. If, however, the utricle and saccule are not completely destroyed, the patient, although he may have no true vertiginous attacks, may be unsteady and have difficulty on forward motion.

There should be no danger from the procedure of labyrinthotomy. There have been reports of facial injury following coagulation of the labyrinth. This is probably either due to improper placement of the coagulating electrode so that it approximates the

relatively mild soft tissue injury to the lips or elsewhere on the face without breaking the skin or mucosa and are familiar to all. They are soft tissue response to trauma. Degree of swelling, ecchymosis and pain are in direct proportion to the extent of the injury. Treatment for the most part is symptomatic. Pain can usually be relieved by the usual analgesics, such as aspirin, but cold applications may help to control the swelling and the pain. Caution is indicated in the use of cold applications when the swelling is pronounced enough to cause tenseness of the skin, as a slough may result in the skin with the already compromised circulation. Soft, light, cool cloths are the most satisfactory. Ice or ice bags are not used on a severely swollen area about the face or mouth because the added pressure may cause necrosis. Occasionally a localized collection of blood may be present in a contused or undermined area, which may be evacuated by needle aspiration, and thereby hasten subsidence. Elastic or adhesive support of contused, swollen lips and undermined areas adds to the comfort of the patient but should be changed frequently enough to be kept clean. The swelling in most contusions subsides in two weeks, but discoloration may persist considerably longer. Persistent discoloration at this stage can be covered by cosmetics.

Lacerations and tears of the skin or mucosa may result from sharp cuts or from a blunt force and need no aids to diagnosis, except in the latter to recognize that there are varying degrees of soft tissue contusion and explosion which may proceed to deep or superficial necrosis. Simple lacerations of the lips and elsewhere about the face, resulting from sharp objects, such as glass, will usually heal if further trauma is not added by the repair. Treatment of simple lacerations consists of adequate cleansing of the surrounding area, irrigation of the wound, minimal débridement, exploration for and removal of foreign bodies which constitute the débridement, ligation of individual bleeding points and careful approximation of the wound edges with deep sutures whenever possible. No viable tissue is cut away. Local anesthesia should be used. The patient should not be hurt. The injection may be made through the open wound with topical application to start with. Facial wounds are never packed open. Dirt blasted into wounds is completely removed to prevent permanent tattooing. Superficial sutures of the finest unabsorbable material practi-

cable (3-0 to 7-0 silk) are placed close to the edges of the wound and a supporting pressure dressing is applied.

Repair of more complicated tears and trap-door lacerations should be made as soon as the patient's general condition permits and follows, in general, the procedure outlined for simple lacerations. General anesthesia may facilitate the repair and be to the patient's advantage. Known points are approximated first as they are recognizable, such as lip, nose and eyelid border, and the remainder of the laceration is closed by successive bisection of the wound. Minimal débridement in facial wounds is of particular importance as features are involved and cutting débridement may create deformities for which innumerable secondary operations cannot compensate (Fig. 1). It is preferable to leave areas of questionable blood supply for later excision, in hope they may survive. Packing wounds open or doing cutting débridement is a general surgical rule mainly for the extremities, to prevent gas gangrene. As gas gangrene does not occur in the face and as features may be lost by either of these procedures, they are not carried out in this region. The débridement is thorough as far as cleansing is concerned, but ragged, torn wounds which elsewhere would be excised are cleansed, sorted out and carefully put back together in their entirety. Trap-door type of lacerations tend to heal irregularly and require a most accurate approximation of all edges. Tears of the lips or lining of the mouth require careful closure of both skin and mucosal surfaces and stay sutures should be put on the inside to try to convert the skin surfaces to the simplest possible closure.

Loss of tissue in facial wounds usually does not require immediate rotation of flaps for closure because of the addition of scarring in the face and possible loss of motor and sensory nerve supply. Partial closure in areas of actual loss is usually preferable, healing is encouraged and secondary repair is done for a superior final result (Fig. 2). Free grafts may be used for coverage and distortion of features is avoided. Widely placed stay sutures are not used on the face, since it is impossible to ever eradicate their marks, which are known as a "ladder effect." If necessary, sutures at a distance from the edges of the wound can be tied over a fold of gauze to prevent permanent suture marks.

Lacerations resulting from a blunt force are usually accompanied by contusion, undermining and, in general, damage to all

The Mouth, Tongue, Jaws and Salivary Glands

By JAMES BARRETT BROWN, M.D.,
and MINOT P. FRYER, M.D.

JAMES BARRETT BROWN is a Mark Twain Missourian, who became a pioneer disciple of the young specialty of plastic surgery. He was educated at Washington University and has devoted his professional activities to that institution and Barnes Hospital. His surgical imagination has opened this field of surgery in many directions and his exacting, meticulous ideals have provided results of the highest standards. Consultant in plastic surgery to the Chief Surgeon of the European Theatre of Operations, it was mainly through his efforts that emphasis was placed upon the care of American wounded with loss of tissue in hospital centers in this country.

MINOT PACKER FRYER, a pupil and colleague of Doctor Brown, is a product of Brown University and The Johns Hopkins Medical School. He is a disciple of the training in the school of plastic surgery, begun by Vilray Blair and developed by Brown, at Washington University.

MOUTH

Soft Tissue Injury. Injury in the region of the mouth does not respect arbitrary anatomic sites in its effect. Compound facial injury is used to describe the result of trauma of any severity, since there is injury to the

soft parts, skin, subcutaneous tissue and fat and to the teeth and underlying bony support of the face and mouth. Division into the affected parts is made only for the purposes of description.

Contusions, or bruises, can result from

Irradiation should be included as an agent of trauma to the lips and mouth. Large individual doses can cause acute inflammation of the part irradiated with progress to ulceration. Small repeated doses after a lapse of years can cause atrophy, telangiectasis, keratosis and ulceration with progression to carcinoma. Treatment is resection of the involved area and repair as indicated. If carcinoma has developed, the area of potential metastatic spread may require resection.

Infection of Soft Tissues. *Pustules* are the simplest form of infection of the soft tissues and may appear in crops. Cleanliness will usually control their spread. *Abscess* of the lips, in the mouth or on the face is a localized collection of pus. There may be a mixture of organisms, but staphylococcus is usually present. Drainage is usually spontane-

ous, but conservative opening may hasten subsidence.

Cellulitis may follow abscess formation in the upper lip when a localized inflammatory process becomes diffuse and spreading. Drainage from here along the angular vein to the cavernous sinus with thrombosis is a potential danger. It was particularly so before the advent of antibiotics. Treatment consists in local atraumatic management and large doses of antibiotics, as the danger of intracranial extension and death is to be avoided.

Jaw abscess, or abscess in the soft tissue around the jaws, is usually related to the teeth, as an extension or penetration of a gumboil or root abscess or due to manipulation of an acutely ulcerated tooth. *Acute pericoronitis* (localized inflammation around

Figure 2. Soft tissue and bone damage resulting from shotgun wound. A, Soft tissue loss less than appears, as often occurs. Careful closure of lining of mouth and face done after minimal débridement around comminuted fracture of the mandible. Features restored as well as possible. B, Segment of jaw blown out by close-range shotgun injury. Remainder of comminuted mandible fixed and collapse of soft tissue prevented by internal wire in jaw. C and D, Watertight mouth; good opening and closing action.

Figure 1 A, Extensive soft tissue laceration and tearing exposing eye, extending into nose and mouth, with partial avulsion of scalp B, Minimal débridement. Repair in one operation by careful closure with fine sutures placed close to edge of wound and approximating known points. Features saved, eye protected, secondary revision of resultant scars unnecessary.

layers of soft tissue. Skin edges are ragged and may be of questionable blood supply, but the same principles of treatment are employed in the repair. All areas which might not survive are left for secondary excision rather than sacrificing a portion that would have lived. Subcutaneous fat may be actually exploded from the tissues and droplets will be seen scattered around the wound and over the clothing. This may occur when an individual is thrown forcefully from a car or suffers a similar accident. Deep cleansing of undermined areas by irrigation with normal saline solution is time consuming but invites early healing. Additional fixation may be secured by adhesive strapped across the wound. Steady even pressure is maintained, particularly over undermined areas, by fine-mesh gauze placed over the wound upon which surgical waste is held with a circumferentially wound soft gauze roll and the dressing is fixed in place with adhesive. This type of dressing is desirable over any area of repair. It is necessary over the site of the more complicated injuries, but may not be practicable over simple lacerations, as in the lip. Sutures can be re-

moved from most lacerations about the fifth day. Those in the mouth can be left longer. The wound may require support for an additional week.

Tetanus protection is routinely given. Prophylaxis against gas infection is given as indicated, but primary gas gangrene is extremely rare in the face. Antibiotics are administered as required.

Lacerations inside the mouth can be approximated to hasten healing but should not be tightly closed. Dependent drainage may be necessary. Repair of salivary ducts should be done primarily, if possible, using a lacrimal probe or small plastic tubing for a splint. When repair is not possible, the proximal end of the duct may be brought into the mouth as a separate opening and sutured to the lining of the mouth or a local flap of mucosa approximated to this end.

Laceration of the tongue may not require suture, unless it extends through the edge of the tongue. The same is true of the soft palate, especially for puncture wounds. A general anesthetic is usually required in children and the choice may be to do the suturing as a secondary procedure.

caused by lack of riboflavin and is manifest by superficial transverse fissures at the angle of the lips with very little inflammatory reaction. Usually 3 to 5 mg. of riboflavin a day is sufficient for cure, but with difficulty of absorption 10 to 20 mg. of the crystalline riboflavin should be given by mouth.

Vitamin C deficiency is recognized in the mouth by the red, swollen appearance of the

gums and interdental papillae; the manifestations may progress to actual scurvy, bleeding, ulceration and necrosis. Treatment is the administration of ascorbic acid by mouth or intravenously. Fresh citrus fruits and tomatoes are added to the diet, if tolerated.

Congenital Deformities and Anomalies. *Cleft lip* and *cleft palate* occur in some combination in one out of 600 to 1500 infants

Figure 4. Design for repair of single complete cleft lip.

a, The V-excision operation. While the columella is held over straight, A is marked at the junction of the skin and vermillion border at the level of the base of the columella. X is in the same relation to the columella on the sound side. A' bears the same relation to the ala on the cleft side that X bears to the ala on the normal side. C is on the mucocutaneous junction at the point where the vermillion border first begins to thin out. C' is on the mucocutaneous junction, the same distance from A' that C is from A. To perform the V-excision operation, A' is brought over to A and C' to C, after excision of the edges of the cleft.

b, The flap operation. The V-excision operation is marked out first. C' is on the mucocutaneous junction at the most medial point of good full vermillion border. B' is on the line A'-C', equidistant from C' and C. The incision is A'-B'-C', saving the amount of lip indicated by the shaded isosceles triangle. B is on the mucocutaneous junction, the same distance from C that B' is from C.

the next step.

d, The lightly incised lines A-B-C and A'-B'-C' are cut completely through the lip with a stab blade, with care to keep the knife exactly perpendicular to lip. All angles should be completely opened. The vermillion border is inspected and any attached skin removed with a stab blade. The rectangular flap freed from A'-B'-C' must be loose enough to be rotated up 180 degrees into the nostril floor. Dotted stippling indicates areas of soft parts undermined.

incision is carried upward from C' to skin. This is also done on the other side (see b). The angle (see b) is to be undermined at

zag fashion, fitting them so that they meet on around the vermillion border.

a partially erupted third molar) is another common cause, as are improperly drained fractures. Bone necrosis and sequestrum formation from a variety of causes may be responsible for abscess formation, e.g., irradiation, heavy metals, specific infections. Extension from contiguous structures, such as obstructed salivary glands, or metastasis in the blood stream from an abscess elsewhere in the body is unusual. The inflammatory process from any of these causes may extend into the neck and cause respiratory difficulty. Treatment consists of large doses of antibiotics and, whenever localization has occurred, drainage of the abscess. Localized collections, such as a gumboil, may be gently drained into the mouth. Otherwise, drainage is external through a small incision made below the jaw in a dependent position. Careful atraumatic exploration of the masseter and internal pterygoid regions is done and a drainage tract is established by leaving a loose pack in the wound for twenty-four hours.

Ludwig's angina is a vague term applied to diffuse swelling of the neck which may compromise the airway and is the result of an undrained abscess. It has become practically nonexistent since antibiotics have been employed. This is a somewhat famous infection of earlier days because the Queen of Luxembourg was treated for it by Ludwig. However, Gensoul antedated Ludwig by six years and designated the brawny edematous cellulitis as septic phlegmon of the floor of the mouth.

Canker sore or *ulcerative stomatitis* is commonly recognized and may be due to a virus alone or in combination with mouth organisms. Treatment consists in attention to mouth cleanliness, the use of mercurial or methylene blue applications and improvement of the general health. Pain may be severe, but not enough to require blocking

or section of the lingual nerve, as has been suggested.

Stomatitis in many forms may occur and may be a manifestation of a general debility, such as anemia or vitamin deficiency. If Vincent's organism is the causative agent, control is achieved mainly by cleanliness and a soapy toothpaste. The fundamental deficiency in general health should be corrected.

Noma is a rapidly progressive gangrenous stomatitis, which is rarely seen, and is an expression of general debilitation or of some blood or metabolic dyscrasia (Fig. 3). Treatment is obviously aimed at improving the general condition and large doses of antibiotics are given. Local treatment is of little value. The former use of cautery excision and of x-ray treatment is of little help in comparison with antibiotics.

Specific infections due to tuberculosis and syphilis are only rarely seen. *Tuberculosis* can cause deep, dirty, ragged ulcers in the mouth, most commonly on the central portion of the tongue, and treatment is that of the underlying disease combined with the use of the newer antibiotics. *Syphilis* or a gumma may be the primary lesion. This produces a foul, discharging, dirty ulcer without the surrounding characteristic hardness of carcinoma. Systemic antisiphilitic therapy is indicated, but healing may be marked after the initial dose of the medication employed. *Granuloma inguinale* with involvement of the lips and mouth has been reported.

Vitamin Deficiencies. *Vitamin A deficiency* may be manifest as keratinization and hyperplasia of the gums and is treated by administering large amounts of the vitamin, 25,000 units daily. However, absorption of the vitamin, particularly in the debilitated, may be limited.

Deficiency in vitamin B complex can cause angular stomatitis and glossitis. *Cheilosis* is

Figure 3. Noma. Progressive gangrenous loss of entire cheek.

tion and/or development of faulty speech habits. All-inclusive rules cannot be made as to time or type of closure, but decision must be made for each individual patient by a competent surgeon, with consultation as needed with the general dentist, speech trainer, otologist, orthodontist and prosthodontist.

Reconstruction of single cleft lip and nose deformity can be followed in Figure 4. In general, a V-excision operation is first marked out and then a small triangular flap is designed just above the vermillion border on the cleft side to save lip at this point, which is necessary for fullness and a normal relationship to the lower lip. A summary of the objectives of any operation for the repair of a cleft lip would be a full upper lip in advance of the lower lip with a flexion crease above

the vermillion border (Fig. 5). The lip itself should be full, without notching, the floor of the nose should be closed at proper level, the ala should be symmetrical and of same level as normal and its direction should be with the curve toward a straight columella. The operation outlined in Figure 4 provides a method for the routine accomplishment of these objectives. The simplicity of the fundamental markings readily allows the repair to be fitted to the deformity. Variations found in each lip can be taken care of on an individual basis.

Repair of double cleft lips (Figs. 6 and 7) is usually not done until the infant weighs about 10 pounds, because of the technical difficulties of the repair and for the safety of the child. Repair of a double cleft lip is about twice as difficult as that of a single

Figure 6 Design for closure of double cleft lip.

a, When the premaxilla is excised, a block of bone is removed directly from the vomer.

b, Flap closure is done on the total side and a V-excision operation on the partial side.

born alive. They may be accompanied by some other deformity. The cause is unknown, and though often present, there should be no parental feelings of guilt. In families, a tendency may follow recessive mendelian progression. Mental capacity of children with this deformity is the same as in the population as a whole. Actual performance in school is usually superior, probably owing to a compensating drive because of the physical deformity. The best possible surgical repair with the steadying influence of constant patience and help in the home usually produces the best of citizens. Over-sympathetic parents, because of their own false feelings of guilt, hinder the child's progress to social adjustment more than does any single factor, except social agencies which brand him as "cleft palate" and thereby single him out from any other children. As in any child, a lifetime of productivity, happiness and acceptance by others more often stems from a home where there is love and a feeling of being wanted.

Embryologically, the lip and upper alveolus are a product of the fusion of two lateral maxillary processes and a central globular segment; this fusion occurs between the ninth and thirteenth week in the embryo. All varieties of clefts of the lip and palate—single or double, complete or incomplete cleft lip and palate or any combination thereof—can result from failure or incomplete fusions of these three elements. Single complete cleft lip and cleft palate is the

most common type. Double cleft lip and palate is more common in males, but incomplete cleft of the palate alone, usually accompanied by an insufficiency or shortness of palate and a somewhat retruded lower jaw, is more common in girls.

Repair of the single cleft lip can be done any time after birth if the infant is in otherwise good condition, and it helps to initiate a normal up-bringing if the child can leave the hospital with the mother. Double cleft lips are repaired when the child is a month old or has shown a real tendency to gain weight. Reconstruction of the nose at this initial operation is as important as repair of the lip. The excellence of the ultimate surgical result is dependent on the primary repair. No number of secondary procedures can compensate for the failure to construct the best possible lip and floor of the nose at this time. This initial repair may set the pattern for the child's whole life. It is not the time or the place for the occasional surgeon to try out his skill.

The palate is usually closed in the latter part of the second year. If done before, tooth buds located toward the midline of the palate are disrupted before they can migrate to the alveolus. The advantages of one's own teeth over a dental plate do not need to be explained to anyone. There may be orthodontic reasons for postponing palate repair until the child is four years old, but these should be weighed against the possibility of hearing loss from constant middle ear infec-

childhood dental care with the preservation of every available tooth. Orthodontia is necessary in some degree in most children with a cleft palate. Teeth in the line of the cleft are usually crooked and require straightening. Maintenance of the dental arch is im-

portant in some children. Speech training can best be carried out in the understanding privacy of the home after parent and child have had a few lessons, or even a single lesson, from a good speech trainer. Hearing measurements should be made if there have

the cleft border by paring. e, Suturing the uvula and upper surface of the palate aponeurosis. d, Denudation of the cleft border by paring. c, Mobilization by division of the palate aponeurosis. b, Denudation of the cleft border by paring. a, Initial incision.

with the blood supply. If there is any doubt of the integrity of the blood supply, it is safer to suture as far forward as the original relaxation will permit without tension and to do the remainder at a subsequent stage, as failure of union is less catastrophic than a slough or

Figure 7. A, Double complete cleft lip and palate B, Lip and nose repaired on both sides in one operation as shown in Figure 6. Palate subsequently repaired.

cleft lip and the result is, unfortunately, about one-half as good. The baby is held up at a 45-degree angle and fed by means of a syringe to which a short piece of rubber tubing has been attached. Gavage is rarely necessary if nursing personnel or the family has the patience to use the syringe method.

Embryologically, the deformity is due to failure of fusion of the median globular and the two lateral processes of the maxilla. The degree of cleft on either or both sides is the result of the incompleteness of fusion and so there can be double incomplete clefts, complete clefts on one side, incomplete on the other; or double complete clefts. The median globular process becomes the pre-maxilla-prolabium segment which is the central part of the lip and palate. This is an integral part of the lip and palate and is necessary for closure. If possible, the lip is closed without disturbing it unless it is too far out of position to allow for closure or unless after closure the pressure of the closed lip will bend the septum and occlude the nasal airways. In such cases it is preferable to set this segment back in a more optimal position, as shown in Figure 6 a.

Closure of the cleft palate is outlined and described in Figure 8. Adequate surgical repair is the only means by which normal physiologic relationship in the mouth and pharynx can be achieved. Dental prosthetics are an expensive supplement but are no sub-

stitute for direct muscle-controlled components of the palate.

Usually the child with a cleft palate tries to talk at a later age than is considered normal. In addition to the cleft, there may be some unknown insufficiencies of development which might explain the inability of some children with a cleft palate to talk as well as others.

The time to close the cleft palate, as previously stated, is usually during the latter part of the second year before definitive speech habits have developed and after the tooth buds have migrated from the palate. Closure may be postponed until the fourth year because of the often cited observation that facial growth centers may be injured by operating before that time. This recommendation has been made on the basis of poorly executed surgical results and those operations which depend upon molding of the palate bone for closure.

Repair of the incomplete cleft palate which includes closure and elongation is illustrated and described in Figure 9. The incomplete cleft palate is usually shorter than the complete cleft and, unless adequate length is provided, speech may be poorer than expected in the complete cleft.

Ancillary requirements of the child with a cleft palate include general dentistry, which seems to be the most neglected. A child with a cleft palate needs the usual

accumulation of food in crevices and pockets. Dental prosthesis may be needed if there is no tissue available for closure. Repeated operations on the soft palate add scar with each procedure and this soft structure eventually approaches the character of an inert prosthesis.

Benign Tumors of the Lips and Mouth. Benign tumors can arise from any of the tissue elements in this location, as is true elsewhere in the body. That is, *papillomas*, *fibromas*, *lipomas*, *myomas* and *nevi* occur, as do benign tumors arising from any mixture of the basic histologic parts. They are usually easily recognized (Figs. 12 and 13). Treatment is usually surgical excision for cure and microscopic confirmation of the clinical diagnosis. This is not complicated except in the removal of large tumors located where features may be included or the airway is a problem. Closure of the defect may be possible following removal of large benign tumors, but coverage with a graft or substitution with a direct flap, or numerous secondary procedures, may be

required for restitution of function and the best possible final appearance.

Nevi are divided into several different types, mostly on the basis of microscopic appearance. *Intradermal nevi* are often raised from the surface, may contain hair and, microscopically, show the majority of the nevus cells in the derma. *Junctional nevi* are usually flatter, do not contain hair and show nevus cells concentrated at the junction of the dermis and epidermis. *Combined nevi* show elements of both of the above. Intradermal nevi may never become malignant, but junctional nevi do and possibly the combined variety may. *Blue nevus* contains characteristic cells and although it looks grossly very dangerous, it probably never becomes malignant. *Sclerosing hemangioma* and *subepidermal nodular fibrosis* may grossly be mistaken for nevi. Treatment is surgical excision with adequate margin of any nevus which is being irritated, bleeding, growing or otherwise changing in character. It is practically impossible to remove all nevi on everyone, but

Figure 10. Cross-lip flap establishing proper balance between upper and lower lips, as diagrammed in , with redundant lower lip. B, Balance created , Profile emphasizes marked imbalance. D, After

Figure 9. A, The whole palate has been loosened from the bony palate, the nasal mucosa opened, the major palatine arteries preserved and the suturing started to carry the palate back. B, The palate is held back with three to five sutures and the exposed bone in front is allowed to cover over. Healing is usually complete in one month. C, The elongated palate is shown, with the posterior opened space much smaller than it was originally.

been repeated middle ear infections and decision may be made for earliest possible palate closure. Prosthetic work is usually confined to tooth replacement and, rarely, it may be required when surgical closure has been improperly done. Most dentists can usually add a plug of some plastic material in any position on a partial or complete upper dental plate.

Pharyngeal flaps may be constructed and attached to the palate when there is insufficient length. Pharyngoplasty attempts surgically to duplicate the ridge in the posterior pharyngeal wall, called a Passavant's pad, seen in some patients with good speech.

Efforts to improve any residual deformity in the lip and nose should be carried out until the best possible result is obtained with the tissue available, so that the patient may be as close to normal as is surgically possible. The best possible initial repair of a cleft lip may require some secondary work and, although the change may be comparatively slight, it is worth while if it makes the patient look more normal. However, one operation each on the lip and on the palate, if properly done, is all that is usually required for the best possible result.

Irregularities in the lip or vermillion border may require smoothing out, or advancement of the upper lip on itself, or disproportion in the size or shape of the nostril may be improved. A cross-lip flap from the lower lip to the upper lip may be required for balance around the mouth because of disproportion of the lips, particularly in the profile (Figs. 10 and 11). The protruded lower lip and retracted upper one give the

most noticeable deformity, more often in the double cleft lip than the single.

Orthodontia often is required to expand and maintain the upper dental arch and to bring the anterior forward. But if there is not sufficient success from orthodontia, ramisection, to set the lower jaw back into a more favorable occlusion, may be required to avoid the appearance of prognathism. This is especially true if the lower jaw happens to be large and forward—prognathic.

Prognathism is protrusion of the lower jaw in relation to the upper jaw. Repair depends on the occlusion. The lower jaw may be placed in proper relationship with the upper by closed section of the ascending ramus of the mandible. If the occlusion is no problem, the bone in the symphysis region can be cut down surgically.

Micrognathia is a short underdeveloped mandible. This may be related to some disturbance in the growth centers of the jaw. Repair, as in prognathism, depends on the occlusion.

A short columella is a characteristic deformity of most complete double cleft lips, resulting in a snubbed-nose appearance, the tip of the nose being down on the lip. The columella can be elongated by a flap taken out of the upper lip and advanced upward along with the tip of the nose. The defect in the lip is carefully closed or covered with a full-thickness graft from behind the ear or neck to obtain the best color and character match of the skin.

Defects in the hard palate, alveolus and fornix should be closed surgically whenever possible to stop leakage of air and food or

resection of the part and a serious operation for the infant.

Cavernous angiomas are beneath the skin, but may involve it. They are composed chiefly of larger vessels (blood spaces), appear bluish-red, are easily compressible and slow growing, may be first noticed at any age and markedly distend with dependency of the part. Microscopically, they are composed of thin-walled vessels or spaces, but they can be an extreme example of benignancy in respect to microscopic appearance and malignancy because of location. A large cavernous angioma of the palate, pharynx, tongue or floor of the mouth gradually enlarges with increasing age and, unless surgically controlled, can kill any time by rupture and drowning the patient. Sections of the tumor removed at postmortem examination show simple, enlarged vessels. Lip involvement with large vessel angioma presents a problem of increasing deformity with growth that necessitates control of the tumor with preservation of a feature.

Treatment of the small cavernous angioma may be by excision of the growth or cautery destruction. As features are involved, usually multiple stages are required for control. "Multiple suture technique" has been of real benefit in those angiomas involving the lip, tongue or elsewhere in the mouth by collapsing many of the vessels, yet preserving the feature or making subsequent excision easier. This consists of placing chromic catgut sutures directly into the growth from the surface and tying them on the surface to obliterate the spaces. The method depends on occlusion by healing of the thin collapsed wall. Interstitial irradiation has been helpful in those angiomas with a small vessel component in which eventual excision is indicated, since the

caliber of the larger vessels is reduced by their collapse and scarring. The larger spaces themselves are not much affected by the irradiation unless a cauterizing dose is used, which should be avoided since the principle of treatment is to control the growth but leave the area intact.

Port-wine stains are the third most common types of angiomas. These are not tumors but rather congenital enlargements or excess of the small vessels in the skin. Mucosal involvement usually requires no treatment, but in the skin of the lip treatment may be indicated because of the appearance. Superficial abrasion has been of some limited value if this addition of scar is of no significance. Cosmetics may cover the redness. Excision and replacement with a graft is the alternative, but it should not be done until all possible spontaneous fading has occurred and until the patient is old enough to understand the cumbersome process and the scarring that results.

These anomalies or tumors may all occur in mixed variety and have to be dealt with accordingly.

The cavernous types tend to get worse with age from gradual destruction and form phleboliths that may be painful and become more prominent on the surface and cause increasing deformity. They may occur deep in the face, pharynx, tongue, parotid and pterygoid regions, go into the temporal fossa and cause severe damage and trouble. There may be thrill and bruit from arterial leaks and, when these occur in the face and around the ear, they are very uncomfortable.

Figure 12. Irritated papilloma of tongue.

Figure 13. Inclusion cyst of tongue.

Figure 11 Diagram of lower lip flap adding bulk and creating proper proportion between lips a, Flap removed from lower lip in triangular shape to allow for closure and, if necessary, it could be designed to fit into the floors of the nostrils b, Lower lip flap in place sustained by inferior labial artery in the pedicle until flap can pick up its own blood supply from the upper lip Lower lip closed c, Pedicle has been cut and vermilion set into proper position

the above criteria can be used in judging the necessity for removal. All junctional nevi should be removed if they could be recognized grossly, but final classification is usually dependent on microscopic appearance.

Cysts, ranulas, angiomas, lymphangiomas, keratoses, leukoplakias, epulides and mixed tumors are benign tumors, but their treatment may present particular problems.

Cysts are usually of the retention variety, readily recognized, and are seen in the lips or anywhere inside the mouth. If small, they are completely excised and the defect closed. Larger cysts may require staged removal or simple "unroofing" may suffice. It is apparent that there may be recurrence of swelling or obstruction to any of the many glands in the area of operation and the patient should be made aware of this possibility. *Sebaceous cysts* occur in the lips as elsewhere in the body and require excision for cure. *Dermoid cysts*, which are deep inclusion cysts, may occur in the lips and the floor of the mouth and require removal.

Ranula is a more complicated type of cyst as far as removal is concerned. It is recognized as a bluish swelling in the floor of the mouth, pushing up the tongue or even extending into the neck. It probably results from some anomaly of the accessory salivary glands and ducts and may develop in a child or not show up until adult life. The fluid is usually clear and may be viscous. *Ranulas* have been controlled by developing permanent drainage with a seton, that is, a heavy silk or wire suture, left in place until the lining of the cyst heals to the oral mucosa. Complete surgical removal may eventually be necessary, but this is often of such

magnitude because of the extent of involvement that preliminary control with a seton or partial removal and packing may be safer.

Angiomas of the different types occur in the mouth and may be an actual threat to life because of position. Growing hemangiomas, called *arterial hemangiomas* because of their bright red appearance, occur about the mouth or lips and are raised from the surrounding surface, but are in the skin (Fig. 14). These hemangiomas are seen in the newborn or infants and may at any time cease to grow and eventually control themselves so that there may be some question as to whether they are true neoplasms, vessel anomalies or hypertrophies. Others of this same type, however, may proceed to ulceration, recurrent bleeding and on occasion lead to death of the infant. They should be treated before destruction of a feature occurs. Microscopically, they are composed of growing small blood vessels and endothelial cells, but the microscopic picture has given no clue as to the eventual activity of the tumor. Treatment should not be withheld if there is any question of progression of this type of angioma and usually a minimal dose of interstitial irradiation, i.e., radon seeds implanted directly into the tumor, will control the growth. Small growing hemangiomas can be excised or completely destroyed with the fine cautery, but if a feature is involved it can be saved with interstitial irradiation. Radon seeds of 0.1 millicurie or less implanted directly into each cubic centimeter of an extensive growing hemangioma in the tongue or spread out in the palate, for example, may avoid wide

the mouth or tongue may be excised and the remainder carefully followed in frequent examinations. If a large area requires total excision, it may be done in stages or a skin graft will be required for coverage of the defect. Irradiation seems to be of questionable permanent value in the treatment of leukoplakia.

Epulis is a benign tumor arising from the periodontal membrane of a tooth and its character depends upon the predominance of fibrous tissue, blood vessels or giant cells in its make-up. It can be then white or red, soft or hard, but is usually pedunculated. Treatment is excision of the tumor and usually removal of the associated tooth and its periodontal membrane.

Mixed tumors occur in the mouth, palate, tongue and lips. Biopsy may be required for diagnosis of large mixed tumors, but small tumors can be completely removed for cure and for microscopic confirmation of clinical impression.

Malignant Tumors of the Lips and Mouth (Figs. 15 to 19). *Basal cell carcinoma* is the most common malignant tumor occurring in the upper lip, as contrasted to the lower lip where squamous cell carcinoma is the most frequent. Basal cell carcinoma probably does not metastasize as such, but, contrary to the usual general impression and report of microscopic appearance, this tumor can kill as surely by local invasion and persistence as can squamous cell carcinoma. Failure to metastasize is no indication of benignancy. Prompt, aggressive treatment is necessary for control. These growths have been reported as metastasizing, but the metastatic lesions probably come from basal squamous growths.

Basal cell carcinomas arise either from sebaceous glands or hair follicles in the skin and do not occur in the mouth. They can

more accurately be divided into three groups on the basis of gross appearance as to expected behavior, rather than by the microscopic picture.

Solid, raised basal cell carcinomas are slow-growing tumors with a tendency to grow up from the surface of the skin and probably are the reason the basal cell carcinoma is viewed with little concern by many. However, it can change character at any time, grow rapidly and become invasive, though previously dormant for years. These tumors are easily excised when small. Radiation may be effective. Later, when extension is wide, plastic surgery restoration of the area may be necessary following excision or radiation.

"Field-fire" basal cell carcinoma has a flat healed central area surrounded by a slightly raised smooth edge of actively growing tumor. Remnants of tumor may remain in the central healed section. "Basal cell carcinoma of multicentric origin" is a term which has been used to describe this tumor. Treatment is excision of the entire area and replacement as necessary. Radiation may be used, but, if a biopsy is necessary, time and expense for the patient may be saved by one surgical procedure.

Invasive basal cell carcinoma was well named rodent ulcer by older clinicians because of its dangerous persistence. In the upper lip, it commonly arises or seeks the nasolabial fold where it eventually invades the pyriform recess and, unless stopped, proceeds to kill the patient over a long, painful debilitating course. Often only a small portion of the tumor presents above the surface of the skin, while a solid, larger invasive component is located beneath the skin and is growing in all directions. The superficial part may or may not ulcerate. Treatment must be aggressive. Radical ex-

Figure 15. A, Basal cell carcinoma of the ala of the nose with involvement of the cartilage and lining. B, Excision and immediate repair with composite graft cut to pattern from the ear. Composite graft supplies lining for nose, skin for outside of the rim with cartilage contained between these two surfaces. C, View of nose from below showing support to graft by strut of contained cartilage in the composite graft. One operation. Staged flap repair avoided.

Figure 14 Growing, bright red, arterial hemangioma. A, Raised, red, growing hemangioma started as tiny red spot in lip. If allowed to progress, may destroy entire lip. B, Control of tumor by light dose of interstitial irradiation. One-tenth millicurie gold radon seeds were used. Lip saved. One procedure.

It may be mentioned again that these constitute a typical example of the microscopic pathologic appearance having no relation to the seriousness of the lesion. These angiomas may be truly malignant by position and extent.

Lymphangiomas can involve the lips, tongue or be anywhere in the mouth. Usually they extend into the neck and consist of multiple, flat, endothelial-lined spaces. They may be associated with a hemangioma or the tumor may actually be a mixture of both, i.e., lymphangioma-hemangioma. Sabin's theory of blood vessel development could explain this association. Lymphangiomas usually appear at an early age but may not show up until later on in life. Small confirmed lymph tumors not involving features can best be surgically excised. Extensive involvement usually requires more than one operation for the safety of the patient. Aspiration and obliteration with escharotics are possible. Limited excision, breaking down the multiple septa and packing with an escharotic pack is often the procedure of choice. *Hygroma* is a lymphangioma of the neck and may extend into the mouth, face or parotid region. Acute respiratory obstruction due to encroachment or pressure on the airway requires immediate relief.

Keratosis are rough, dry, raised areas which appear on the lips with advancing

age. They are more commonly noticed in persons whose faces have been exposed to the out-of-doors. Certainly most keratoses never become malignant, but likewise most squamous cell carcinomas of the lips have developed on a pre-existing keratosis. Treatment is simple cauterization of the keratosis or, if there is any question of change to carcinoma, then excision for microscopic examination should be done. This simple surgical procedure is much more important in the over-all control of cancer and will save more patients than any extensive ablative procedures that can be done after cancer has developed.

Leukoplakia is readily recognized as flat or slightly raised white patches occurring anywhere in the mouth. It may be a small solitary spot or involve most of the mouth and tongue and may be a response to some irritation. Progression to carcinoma is possible any time and the patient should be cognizant of the potentiality of this lesion. Initial treatment consists in the removal of any known irritant and mouth cleanliness. Smoking should be stopped, or at least cut to a minimum. The teeth should be cleaned, cavities filled and any sharp teeth or fillings removed or smoothed out. Small patches may be excised for microscopic examination. The more dangerous-appearing or piled-up areas in extensive involvement of

Figure 18. Carcinoma of the lower lip. Flat ulcer type, edges piled up. Oval excisional biopsy should be done which may suffice locally or further excision or irradiation may be required. Decision as to time for bilateral upper neck dissection can be made any time.

for infection, dyscrasia or irritation, then it should be removed entirely or as a specimen for microscopic diagnosis.

As to treatment of all malignant or potentially malignant tumors, cure depends on staying outside of the tumor field in the treatment, whether surgical or radiation. If the tumor field is entered or some of it left behind in a small area, or if a small area has not been controlled by radiation, then a primary cure is not obtained.

For recurrent tumors, the same rule applies of still staying outside the tumor field.

For metastatic areas, the same rule still applies. The ideal operation for any advanced malignant lesion is block resection of the growth and its regional lymphatics. Unfortunately, there are few such possibilities, but carcinoma of the buccal mucosa presents one of the best possibilities for this procedure.

Neck dissection, or removal of the lymph-bearing area in the neck which drains from the lip, may be the most important factor in the patient's cure. If neck metastases are palpable in a patient with carcinoma of the lip, a neck dissection should be done immediately or as soon as it can be determined that the local lesion can be controlled. No blanket rule can be made as to which patients without palpable metastases should have a neck dissection, except that all patients with a carcinoma of the lip are and remain candidates for a neck dissection as long as they live. This statement is substantiated by numerous long-term follow-ups. Statistics are available showing that 80 to 90 per cent of patients with carcinoma of the lip do not have neck metastases, but

the physician in charge of the patient with a lip carcinoma should consider this patient as he would a member of his family who might be in the 10 or 20 per cent group in which metastasis to the neck occurs. Decision as to the necessity for neck dissection must be made on an individual basis. Various factors help with this decision, among which are: age—the young patient is more likely to have early metastasis than is an older one; duration—the longer the carcinoma has been in the lip the more likely it is that metastasis has occurred to the neck; nature of the lesion—in the small ingrowing ulcer neck metastasis is more likely than in the more outgrowing type of carcinoma; availability for follow-up—some patients will be less faithful in returning for follow-up than others, for one reason or another, and in these it would be safer if a neck dissection were done; experience of the surgeon—the experience and ability of the surgeon probably comprise the most important single factor, since the usual bilateral upper neck dissection done for carcinoma of the lip should be associated with no mortality and require around a week's hospitalization.

A bilateral upper neck dissection is usually adequate for control of the area of spread from a carcinoma of the lip. Depending on the location of the primary tumor, metastasis can be to one or both sides of the neck. The operation can easily be varied to include all the lymph nodes on one side with the jugular vein, if necessary, and the upper part of the neck on the other. Again, selection of operation is made on an individual basis. A bilateral upper neck dissection includes all of the nodes to which carcinoma of the lip usually metastasizes first. This would embrace the region of the omohyoid muscle up to the jaw on both

Figure 19 Cross-lip flap for immediate reconstruction, deep excised (d area) revision

Figure 16. Carcinoma of lower lip. Outgrowing fungating epidermoid carcinoma of lip

cision may be combined with irradiation. Interstitial irradiation with the use of 0.5 or 1 millicurie gold radon seeds may stop the deeper extension and avoid some secondary reconstruction. Composite grafts can be used for immediate total reconstruction following removal of tumors involving full thickness of the nose, thereby avoiding complicated flaps and numerous operations (Fig. 15). Thoughts of reconstruction are always secondary, however, to the most effective means for controlling the tumor.

Basosquamous carcinomas do occur in the upper lip but are more common in the upper part of the face. This classification is on the basis of microscopic appearance in which elements of both basal and squamous growth are present. Grossly, they look like solid basal cell carcinomas which have a history of fairly rapid growth. They do metastasize, but do so as squamous cell carcinomas. Treatment is surgical excision of the local tumor and the regional nodes, as indicated. Irradiation may be effective in cancer dosage and wide application, but the tendency to recur is high.

Malignant melanomas occur in the lips

and the possibility of effective control or cure is relatively high. The local lesion can be radically excised and the potential lymph-draining area resected, if necessary, en bloc.

Squamous cell carcinoma is more common in the lower lip than on the upper and is easily recognizable. There is no question of its potentialities. It usually occurs as a fissure, flat ulcer, or chronic leukoplakia that finally becomes malignant or a fungating mass. There need be little discussion as to the treatment of the primary tumor. Biopsy is required and removal of the entire tumor at this time is indicated if the extent is not too great and there is real question about the malignancy of the individual tumor. Complete excision for the biopsy may be the only treatment required, completed in one operation, and availability of the entire tumor may invite a more positive microscopic report from the pathologist. After a positive diagnosis has been made, decision as to the necessity for more radical excision of the lip or some form of irradiation can be made. V-excision of carcinoma of the lip is not planned for cure, but rather as a repair of a deformity.

Interstitial irradiation, as 0.5 millicurie of gold radon seeds and external x-ray and radium therapy, has repeatedly saved lip and reduced the necessity for secondary substitution operations.

It has been repeatedly stated that all carcinomas of the lip should be cured, and so they should. But they should also be prevented by early removal of suspicious lesions. As the safest procedure for all lesions of the face, mouth, tongue and jaws, the following may be taken as fundamental: If a lesion persists for two weeks and, at the outside, four weeks under usual treatment

A

B

p by epidermoid carcinoma. Car-
Defect in lip following excision of
ation No secondary reconstruction

usual symptom is pain, and diffuse enlargement of the circumvallate papillae is seen, sometimes localized to one area or the other.

Irritation by strong chemical applications, cauterization or removal is contraindicated as the scar produced may make the process worse. At present there is no known preventive or medical cure. Treatment consists of general mouth cleanliness, including no smoking, care of sharp teeth or fillings and, of course, close observation and the removal of any active lesions. Sometimes the lesion may be widespread and thick and approach the process of verrucous carcinoma, the whole surface of a cheek or tongue may be involved.

Removal and repair with a free skin graft may be required. These widespread deep involvements require active treatment or removal, since they will frequently become cancerous. This is one example of being able to remove or control a disease but not knowing how to prevent the tendency.

Carcinoma of the Tongue. Carcinoma of the tongue is usually seen as a fissured ulcer with tissue piled up along the edges (Fig. 20). The margins of the ulcer may be overhanging, bleed readily, may be sloughing and may be painful. The lesion may be a solid tumor, but usually ulceration has occurred. The most common location on the tongue is along the edge in the molar area, but the lesion may occur as a solid mass in the center of the tongue or anywhere else. The ulcer or solid component may extend to the floor of the mouth, over the alveolus, up the tonsillar pillar or backward to the epiglottis or pharynx. When it is located in the back of the tongue, there may be no pain until there is extensive development and even metastasis. This area may be practically a "silent one" as far as discomfort is concerned and the first symptom may be the appearance of a metastatic lump in the neck.

Lesions of the face, mouth, tongue and neck can be easily seen and palpated, biopsy is easily done and the presence and nature of none of them need be missed.

Any ulcer or area of growth in the mouth should be biopsied if present for three weeks and if it has not responded to usual methods of treatment for inflammation, nonspecific or specific, or for lesions of dyscrasia, allergy or drug reactions. If there is no question as to the diagnosis or real evidence of growth, there is no reason to wait until the end of this arbitrary period. There also should be no further delay if the patient has

waited this maximum period before being seen for the first time. Suspicion by the examining doctor or dentist that carcinoma may be present is as important in the control of cancer as encouraging the lay public to be on the lookout for such occurrence. Likewise, wishful thinking that a lesion is not cancer has no place in dealing with lesions that possibly are cancer. Progression to inoperability may be very rapid once the patient has noticed something wrong.

The method of taking the biopsy specimen is important. Small lesions may be totally excised since carcinoma may be present in a small area of leukoplakia or of an inflammatory reaction, and if carcinoma is not present total excision may effect a cure. Adequate sections should be taken from the most suspicious parts of larger tumors. Repetition of a biopsy is preferable to overlooking a carcinoma.

The cell type is usually that of the squamous variety with more or less pearl formation. In or around the tonsillar fossae there may be little hornification of the cells. These tumors have been called transitional cell carcinoma or lymphocarcinoma since they contain small round cells. Tumors of this pathologic type, as would be suspected, are particularly sensitive to irradiation but tend to recur and metastasize readily. The more differentiated the individual tumor, the better the chances of control. Adenocarcinoma is infrequent but occurs usually in the body of the tongue. Sarcoma of the tongue is rare.

The position on the tongue is mentioned because of prognosis. The further forward

Figure 20 Carcinoma of the tongue. Typical ulcer with a solid component beneath a surrounding visible area. Primary carcinoma could be controlled with 1 millicurie of gold radon seeds implanted directly into the tumor and area of potential invasion. The patient will need a complete neck dissection.

sides and the superior deep cervical chain of nodes with the contents of the submaxillary triangle en bloc. There is minimal scar and no actual disfigurement. The term "suprahyoid dissection" does not describe the operation because in this procedure a serious potential area is left in the center of the neck. The term "upper or supraomohyoid dissection" is preferable.

It is almost needless to state that a cure for carcinoma would be as welcome in this field as elsewhere. But until this is forthcoming, radical surgery, neck dissection and sufficient restoration must be included in the procedures that may give the patient a chance of survival.

Sarcoma of the mouth and lips is rare but may occur. Usually it appears as a solid, hard enlargement which does not tend to ulcerate. It has been seen arising from soft tissue elements following irradiation. Diagnosis is usually made on biopsy. Treatment is usually surgical excision because most types of sarcoma are resistant to irradiation.

Carcinomas of the cheek, alveolus and floor of the mouth are considered together as these regions are often involved by one carcinoma because of anatomic proximity and the treatment is often similar. *Buccal carcinoma* occurs more often in the older age group than in the younger and may be slow growing and warty in appearance, even fungating out into the mouth. This latter type is called verrucous carcinoma. Deep invasion into the cheek may be late, but there may be extension down over the alveolus into the bone and into the floor of the mouth. Treatment of verrucous carcinoma can be local en bloc excision of the tumor. If bone involvement is suspected, the mandible may be included in the resection as may the floor of the mouth. When metastasis or extension into the neck is present, the en bloc removal can be combined with or considered a part of a complete neck dissection on the involved side.

Carcinoma of the jaw is an extension of carcinoma of the buccal mucosa with early involvement of the bone. When the first lesion is on the gum, the extension is to the alveolus early and the lesion is sometimes called alveolar carcinoma. Alveolar carcinoma itself usually originates from a flat-type ulcer, but it may arise from leukoplakia as often do buccal carcinomas.

Carcinoma extending from the cheek or floor of the mouth, and secondarily involving the alveolus, invades the bone much later. Attention of the patient may be called to the carcinoma by a tooth socket that fails

to heal. Bone involvement may be considerable when this type of carcinoma is first seen and x-ray examination may not give a very good indication of the actual wide extent. The best treatment is a combined operation in which the primary alveolar tumor and involved mandible are removed and a complete neck dissection is executed in one block. This is the same type of complete radical neck dissection advised for carcinoma of the tongue.

Carcinoma of the floor of the mouth may start laterally or anteriorly to the tongue and the bone is involved often very early. Therefore, a combined operation with removal of the primary tumor and involved mandible and complete neck dissection is necessary for control. Metastasis also occurs early in the course. If the mandible is not implicated, the primary tumor may be controlled with radon seeds and complete neck dissection on the involved side may be done. In recent literature, the term "commando operation" has been used to describe the basic operation but has no informative value other than that a radical operation is necessary.

Carcinoma of the hard palate and upper alveolus is similar to alveolar carcinoma. Recognition of possible extension of carcinoma of the upper alveolus to the antrum or pyriform recess or pterygoid region is of particular importance. Early bone involvement by the tumor is usual and cure necessitates its removal. The local area is usually left open for constant inspection, but food and saliva leak can be prevented by a dental plate made to fit into the defect. Later repair can be done with a local flap or, if this is not available, a distant flap, as from the arm. Neck dissection, as is done for carcinoma of the tongue, will eventually be required.

A low grade carcinoma such as that not infrequently seen covering a fairly extensive area of the hard palate may be locally excised and the lining to the nose and antrum preserved.

TONGUE

The effects of *trauma* and *infections* upon the tongue and the appearance of the tongue with *vitamin deficiencies* and *congenital abnormalities* have been considered. *Benign tumors* found in the tongue are also the same as those described elsewhere in the mouth.

Hypertrophied circumvallate papillae are frequently seen and often overtreated because of failure of proper diagnosis. The

shielding the remainder of the mouth and treatment is often followed by protracted painful dryness and other effects of irradiation directly on uninvolved mucous membrane. Surgical excision of carcinoma of the tongue can be done adequately, but the magnitude of the operation itself, the mutilation resulting and the repeatedly superior results obtained with radon usually obviate the necessity for operation. Involvement of the jaw by extension of a carcinoma of the tongue or failure of radiation may require extirpation. Glossectomy or hemiglossectomy has been rarely necessary during the last twenty years.

Neck dissection is necessary for the cure of carcinoma of the tongue and is as much an integral part of the treatment as is treatment of the primary tumor. Over 60 per cent of carcinomas of the tongue metastasize

to the neck, usually to the same side as that in which the primary lesion is located and only occasionally to the opposite side. The time to do the neck dissection is the same as that of treatment of the primary tumor, unless it is felt that there is considerable doubt that the tongue lesion can be controlled. Postponement should not be longer than a month, particularly if metastases are already present in the neck. The technique of complete neck dissection for metastatic carcinoma has been described in detail. It should be common knowledge that removal of all the lymph-bearing area from the clavicle to the base of the skull, yet with preservation of vital structures, is necessary for cure. Adequate removal of the deep cervical chain is impossible without removing the internal jugular vein. Figure 21 shows the extent of removal and identifies

Figure 22. Combined operation for removal of carcinoma of the jaw and complete unilateral neck dissection. Complete removal of the potential metastatic nodes from the clavicle to the base of skull including the sternomastoid muscle, jugular vein and contents of the submaxillary triangle, with transection at the base of the primary tumor in the tongue, floor of the mouth or alveolus. The mass from the neck. The opening into the mouth is closed with wire placed in the ends of the bone to prevent collapse. Tracheotomy is usually avoided. The structures remaining in neck are identified in Figure 21. The neck flaps are carefully closed and a firm pressure dressing is applied.

Figure 21 Complete unilateral neck dissection. Internal jugular bulb ligated and divided near the base of the skull. The submaxillary duct and chorda tympani branch of the lingual nerve are divided and the freed anterior segment is rotated out and up onto the external surface of the mandible. The mass containing the

on the tongue, other things being equal, the carcinoma is located, except for involvement of the floor of the mouth, the better the chances of cure. This may be due in no small measure to the inescapable fact that the nearer the tip of the tongue the lesion is located, the sooner it will be noticed. Epidermoid carcinoma primary in the base of the tongue or pharynx may first be found after metastasis has occurred in the neck. This also is of particular importance as far as prognosis is concerned with carcinoma primary in this location.

Treatment of the primary tumor is usually most successfully done with interstitial irradiation in the form of radon seeds. A

calculated dosage is given to the tumor, usually by direct implantation of 1 millicurie of gold radon seeds, using one seed per cubic centimeter of tumor and tissue to be irradiated, 1.5 millicurie seeds are also used. Use of radium needles in the treatment of the primary tumors has been given up to a large extent because of the difficulty of maintaining accurate position in and around the tumor and the extreme discomfort to the patient during their period of application in this sensitive mobile structure. Use of external irradiation remains an alternative if radon is not available. In the employment of x-ray therapy on the primary tumor, there is apparently considerable difficulty in

but they are usually retained to give aid in the fixation of the fracture. They may be removed later.

Reduction of fractures in the body of the mandible is accomplished when the teeth have been replaced in normal occlusion for the patient. Reduction of the edentulous jaw or positioning of the teeth may be done by palpation, under direct vision.

Fixation after reduction, if teeth are present in all fragments, is most simply done by interdental wiring. Steel wires, no. 24 or no. 26 gauge, are twisted around the necks of apposing teeth and the lower jaw is wired to the upper jaw, using the upper as a splint for the lower. The bicuspid or premolar teeth, if available, are the most satisfactory teeth for wiring. Loops may be made of the wires and rubber-band traction can be used for fixation or for gradual reduction. There are many forms of wiring and of bar appliances, but the basic procedure is to reduce the fracture so that the teeth will come up into proper occlusion and be held there. Other means of fixation must be used if usable teeth are not present, even to wiring dentures in place with circumferential wires around the jaw and denture.

Internal wire-pin fixation has been found the most satisfactory supplement in fractures near the angle of the jaw or posterior to molar teeth; in fractures at the symphysis where nonunion can frequently occur without solid fixation; if there is extreme comminution of the mandible or widespread opening into the mouth; if there has been necessary delay in reduction and fixation, or in the edentulous jaw. Use of the wire-pin for fixation is not difficult but does take some practice. After the fracture has been reduced, a 0.05- to 0.08-inch steel wire is driven with a power drill through both fragments across the fracture site below the nerve canal. Multiple wire-pins may be needed in complicated fractures. Open mouth and some chewing are possible during the healing period. Circumferential wires have been used in conjunction with interdental and internal wire-pin fixation.

Direct wiring or using complicated, expensive external fixation or traction apparatus is usually unnecessary. Metal plates with screws have not proved consistently successful in fractures of the human jaw, as they tend to become loose and infected.

External drainage is considered in all mandible fractures. It is almost impossible to break the lower jaw and not have an

opening into the mouth, particularly around the teeth. Drainage can be instituted simply by making a small incision beneath the jaw and carrying the opening up to the fracture site by blunt dissection and putting a small drain to this spot. Protracted healing and osteomyelitis can be avoided by this simple procedure. Obviously, with the aid and protection of antibiotics, this external drainage is omitted in many patients, but this is a deviation from the rule, rather than that drainage is the deviation.

Condyle fractures are suspected if there is a history of trauma to the jaw followed by pain in the side of the face or near the temporomandibular joint and change of occlusion or bite. This is especially true in subjects who have received blows to the chin, or to the "button," in fights. Spontaneous fracture is rare. Condyle fractures are often associated with other fractures of the jaw and their presence must be ruled out if only one fracture is seen, as in the body. The condylar neck is one of the weaker areas of the jaw and consequently is more likely to be broken even though the trauma be indirect. It is usually sufficient to wire the teeth in the patient's normal occlusion for three weeks, then to allow normal return of jaw action. Only very occasionally is open operation necessary and, even if thought necessary, a trial of wiring in occlusion may be done. Operation usually consists of exposure of the condyle, avoiding damaging branches of the facial nerve, and removal of the small upper fragment. Fixation, satisfactory for solid union in this location, is practically rarely possible and is unnecessary. Fracture of both condyles is an extremely serious situation and fixation in occlusion is especially indicated to try to prevent permanent deformity.

Temporomandibular Joint Disorders. The *auriculotemporal pain syndrome* is probably the result of erosion of the temporomandibular meniscus and joint and irritation of the auriculotemporal nerve. Diagnosis may be difficult, but the patient usually complains of severe pain about the ear and temporal region and radiation down into the tongue. Opposing molar support may be lacking and can be tested by seeing if relief is obtained by opening the mouth and swinging the jaw from side to side or by building up the molar region with rubber mats or plugs. If relief is obtained by either maneuver, permanent build-up of the molars can be done by the dentist or, if the patient is edentulous, new teeth can be provided.

the remaining structures. Figure 22 shows the combined operation for removal of carcinoma of the jaw and complete unilateral neck dissection. Deformity following this radical operation is minimal. Bilateral complete neck dissections have to be done at times, but it is safer if the jugular veins on both sides of the neck are not removed at the same operation.

JAWS

Fractures of the Mandible. Because of the exposed position of the lower jaw, fractures of this structure are frequent. The type of fracture depends on the point of contact, the force of the trauma and the relative strength of various parts of the jaw. Displacement of the fragments also is the result of the type and force of the trauma with the addition of muscular pull.

Diagnosis of a fractured mandible is usually not difficult and can be made on examination. X-ray examination, in the postero-anterior, right and left lateral positions, is routinely made. Special views of the condyle and temporomandibular joint may be necessary. The mandible is likely to be broken in more than one place and if one fracture is demonstrable, the presence of a second must be ruled out. The inferior alveolar nerve may be severed and if there is numbness of the lower lip, this should be recorded.

The time for reduction and fixation of a fractured jaw is as soon as possible, if the general condition permits. Swelling in itself is no contraindication to immediate repair. Postponement may make reduction more difficult and eventually fragments may be permanently fixed out of position or non-union of the bone will occur.

The airway may be of primary concern in patients with a fracture of the mandible. Bilateral fracture of the body of the lower jaw and the resultant loose central segment allow the tongue to drop back and occlude the airway. Immediate temporary fixation, positioning of the patient with the head down, traction on the tongue, or even tracheotomy may be necessary for survival, particularly in an individual with a shattered lower jaw. Blood in the mouth resulting from soft tissue tears, as is often found in persons with displaced mandible fractures, and secretions may actually drown a semiconscious patient unless they are sucked out or allowed to drain out by putting the head down, or a tracheotomy opening is made. Accumulation of blood, or even air in the neck, may occlude the airway by

compression and necessitate a tracheotomy. Tracheotomy may be needed at any time, but fortunately this procedure is not usually necessary.

Hemorrhage with a fractured mandible may require immediate control. Displacement of sharp fragments, which may cut major vessels in the neck, necessitates adequate exposure and individual ligation. Bleeding into the neck may be more dangerous by compression of the airway, as mentioned above, than is bleeding to the outside.

The general condition of the patient is of next consideration when the airway has been provided for and hemorrhage has been controlled. Complete physical examination is done to rule out the presence of intra-abdominal or chest injury and, if either is present, the necessity and the time for repair are decided. Fractures or injuries of the extremities may require treatment before, after or during jaw or facial repair. A careful, complete, neurologic examination is made in all patients having facial injuries or jaw fractures. If brain damage is suspected the advice of a neurosurgeon is sought. For snap blows in which the head is forcefully flexed, cervical spine x-ray films should be studied, as fractures may occur in the spine and, when present, may be a serious complication.

Anesthesia for reduction and fixation of simple fractures of the jaw may be secured by procaine block of the dental nerves or of the second and third divisions of the fifth cranial nerve as they leave the skull. General anesthesia may be preferable and decision is made as to whether general or local anesthesia would be better for each individual patient. An airway must, of course, be provided by a tube placed in the trachea, either through the nose or mouth, if general anesthesia is used.

Teeth may be involved in any fracture of the jaw or may in themselves be the extent of the injury. Chip fractures of the teeth can often be smoothed off by a dentist. Cracked teeth may be serviceable for years. If a tooth is loose, many times it will become solid again and stabilization with wires or an arch should be done. Single anterior teeth actually knocked out may be replaced in their sockets if available following the accident, as they may become serviceable again. However, this does not condone the practice of using another individual's teeth for re-implantation. Teeth in the fracture line of the jaw will probably eventually be lost,

other facial fractures, but usually in no way indicate the extent of the actual damage. There may be multiple small chip fractures with fragments no larger than a fingernail and these are not usually seen on the x-ray film. In a badly crushed face there may be twenty to forty small fractures, like a broken egg or glass. Fracture lines through dense portions of bone may be seen, as may irregularities of the orbital borders and antral cloudiness. Reduction may involve pulling the face forward and the upper alveolus up or down, depending on the displacement. No preconceived routine is applicable, the reduction involves reversing the action and force of the trauma.

It may be said that in these fractures, as in most other trauma, basically the surgeon attempts to do the opposite of what the trauma did.

Fixation, particularly in severe facial crushes, requires all means of stabilization. The dental arch can be held, using the lower jaw as a splint, with interdental wires. Internal wire-pins anchored in any stable point, such as a zygoma, can hold other loose points by cantilever action. Also several loose sections of the face can be stabilized in one plane by internal wire-pins driven horizontally across the face (Fig. 23). Needless to say, reduction or elevation to proper position is necessary before the permanent wire fixation is done. External and overhead traction apparatus is used by some surgeons.

Zygomatic arch fractures are mentioned to distinguish them from those displacements of the zygoma itself. Arch fractures usually result from direct trauma, such as that incurred by a fall on a curb or a blow

Figure 23 Extensive crushing of face, nose and frontal sinus, as shown on roentgenogram, of a back-seat passenger in a traffic accident. The patient was seen after seventeen days and operation was performed with the subject under endotracheal anesthesia. The nose and face were

cross-wires
wires. This
was out of

X-ray examination of the joint may be helpful in making the diagnosis.

The *temporomandibular meniscus syndrome* results from derangement of the meniscus and may be acute following a difficult dental extraction or external trauma or may appear suddenly in chronic progressive derangement. Cracking or popping, pain and blockage with the jaw open or closed are the usual symptoms, appearing often in that order as the disease progresses. Treatment consists in rest of the joint by avoiding wide opening, minimal chewing and wearing a chin-vertex bandage. Enforced rest with interdental wiring in occlusion may be necessary. Injection and joint operations have not been very successful.

Anterior dislocation of the jaw may be a part of the temporomandibular meniscus syndrome or may result from trauma on the jaw while the mouth is open or from the pull-scar neck contracture. One or both sides of the jaw may be involved. Diagnosis is usually apparent, since the mouth is held open with the lower jaw forward, or pointing toward the unaffected side in unilateral dislocation. Inability to swallow or talk is usually present at first. X-ray films may be exposed to rule out the possibility of fracture of the neck of the condyle. Treatment, if there have been recurrent dislocations, might be carried out by the patient, since oftentimes the condyle slips back easily. Downward, backward pressure in the molar area may reduce the dislocation or a general anesthesia may be necessary to accomplish this. Protection and rest should be given to the joint as described above. If reduction is impossible, open operation may be necessary and the condyle may be removed. Trauma to the chin with the mouth open may drive the condyle up through the base of the skull into the brain and this dislocation may be called an *anterosuperior one*. Treatment is usually directed toward the brain damage. Later, reduction can be done and occasionally repair of the glenoid fossa is necessary.

Posterior dislocation of the jaw usually results from a forceful smash on the chin when the mouth is closed. The condyle is driven back into and crushes the bony portion of the ear canal. Reduction is often spontaneous, but recognition of what has occurred is important so that steps may be taken to prevent permanent occlusion of the ear canal. Treatment usually consists of opening the ear canal and maintaining its patency. Reduction of condyle dislocation

may require surgical exposure and possible removal of the condyle.

Fractures of the Upper Jaw. Fractures of the upper jaw are a part of middle-third facial fractures except for the occasional separate upper alveolar fracture.

The diagnosis of fractures of the upper jaw may be difficult because of swelling; however, palpations and suspicion that a fracture may be present following fairly severe trauma are of the most importance in making the diagnosis. X-ray examination may not give as good an indication of the type or severity of the fractures as will simple palpation because of superposition, but it is routinely made. Posteroanterior views of the facial bones showing the orbital borders or a modified Waters' film are the most valuable.

Upper alveolar fractures may involve any or all of the alveolus. Extension up into the pyriform recess or medially through the palate is common. The diagnosis is obvious on even cursory examination and palpation. Although minimal débridement in facial injuries is urged, removal of loose alveolar fragments may avoid troublesome drainage and future trouble. Reduction and fixation with interdental wires using the lower jaw as a splint are done if necessary and possible. Internal wire-pin fixation has been used as the only or supplementary means of fixation.

Transverse fractures of the upper jaw and face are frequently seen in persons involved in an automobile accident. These fractures usually result from striking the face on the dashboard, steering wheel or rear of the front seat. The diagnosis can be made on the basis of history of trauma, swelling and examination. Fracture lines may be palpated and movement of separate segments of the face or jaw can be seen. The line of fracture may start in the alveolus on one side, extend up into the pyriform recess and up into the orbit—a pyramidal fracture. If the main force is at a higher level, the nose will be crushed down into the face and the face will be completely detached from the skull. This separation can be demonstrated by grasping the teeth and moving them up and down, but this is not appreciated by the unanesthetized patient. The fracture line in this fracture extends across both orbits. In severe facial crushes there can be any combination of these transverse facial fractures and they are often associated with a fracture-dislocation of one or both zygomas. X-rays are routinely taken, as described for

mask the flatness of the cheek, but the displacement can usually be felt. In addition to flatness of the cheek, which will be obvious when the swelling subsides, diplopia due to elongation of the orbital cavity with downward displacement of the zygoma and with the eyeball following on down into the antral region, difficulty opening the mouth due to impaction of the zygoma on the coronoid, and infra-orbital nerve paralysis due to crushing by the dislocated zygoma may be present. All of the above signs or symptoms should be tested for and recorded, since only one may be elicited. Disability will be permanent unless the deformity is corrected. X-rays, made with the patient in the postero-anterior position or the modified Waters' position, showing the orbital borders of the facial bones, are of the most practical value and are taken routinely. Here again, any x-ray film many times does not give a very good indication of the extent of the damage.

The time the repair should be made is the same as that for fractures of other facial bones, i.e., as soon as the patient's general condition permits.

Minimal débridement is done in facial fractures. Completely detached bits of bone may be removed, but if there is a chance of survival they are left, if necessary, for removal secondarily. Three weeks is about the limit of time at which the zygoma can be reduced from its displaced position. Earlier than this is preferable.

Reduction should be done by the simplest possible method and will suffice if impaction occurs. A large jaw hook pushed through the soft tissue can elevate the zygoma by grasping the inferior border and probably provides the simplest direct approach to the zygoma. There are numerous other operations for reducing the zygoma, but if impaction in the normal position does not occur, a method of fixation is needed. Reduction and fixation are usually possible through entrance into the antrum through the fracture line in the buccal fornix. This requires only a short incision through the buccal mucosa. From inside the antrum, the displaced zygoma can be elevated with a palate elevator or Kelly clamp, the surgeon using his free hand for guidance as to proper position. The correct position can be maintained, until solid union occurs, with an iodoform pack incorporated with balsam of Peru lightly accorded into the antrum. The pack acts as an internal splint and makes it possible to "mulch" into proper

position the multiple comminuted fragments in the floor of the orbit and antral walls. This pack should be removed in ten to twenty days. Multiple internal wire-pins driven across the face using the opposite zygoma as a point for cantilever support have given sufficient fixation alone or may be used in conjunction with other methods. When both zygomas are loose, wire-pins have given enough fixation for solid union to occur and in severe facial crushes have even provided an initial point on which to base fixation of other shattered features.

Nasal fractures are probably more often overlooked than they are diagnosed. Bleeding from the nose following trauma to the part is the result of fracture, or laceration of the mucosa by one of the bones or cartilages, and careful examination may be required to ascertain the cause. Airway obstruction by the bent septum should be corrected and other depressed supports to the nose should be elevated. Maintenance of the reduced position can be provided by intranasal packing and an aluminum splint applied over the nose. In crushes of the nose with extreme comminution, the fractured segments are raised up out of the face and often require further support. No. 26 steel wire passed beneath the nose and anchored over lead plates on the outside of the nose may act as a cradle, with the nose resting on the wires.

Fractures of the nose are further illustrated in Figures 26 A, B and C. Injury to the soft parts, as in Figure 26 A, illustrates the necessity for their accurate reposition as well as that of the underlying supporting framework. The x-ray shows marked displacement of the fragments.

If bone fragments, comminuted as they usually are in nasal fractures, remain displaced and depressed, secondary build-up is necessary, as shown in Figure 26 B. If the dorsum is distorted and enlarged as in Figure 26 C, whether it was due to a fracture or a racial characteristic, cut-down and straightening can be done.

Jaw Infections. Osteomyelitis (Fig 27) is most commonly caused by infections dependent on the teeth or by fractures of the jaw, but it may be associated with cysts in the jaw or follow injuries to the mucosa or infrequently result from infections elsewhere in the body such as in the paranasal sinuses. Other causes may be heat and irradiation.

The most common infecting organisms are staphylococci or streptococci, but others infrequently seen are the *Mycobacterium tu-*

Figure 24 Method of reducing dislocation of zygoma. This is the simplest direct method applicable when fragments will impact in the reduced position. The position of the heavy hook beneath the flange of the zygoma after piercing the skin is shown. Reversing the direction through which the dislocated zygoma has passed by pulling on the hook, the zygoma is guided into impacted reduction with the fingers of the other hand on the upper border of the bone. This is the method of choice for the usual zygomatic arch fracture, avoiding an incision above the hairline. However, extreme care should be taken to keep the upward pull of the hook controlled at all times. Failure of the fragments to impact by this method or any other type of reduction necessitates changing to the approach through the fracture line above the canine fossa, which allows for fixation by the use of an internal splint in the form of a pack in the antrum.

with the fist. The deformity can be palpated through the swelling and x-ray pictures can be taken to compare the arches. Treatment consists in direct elevation of the depression in the arch with the hook through the skin (Fig. 24) or a large towel clip can be used. There is no scar. Impaction usually occurs and nothing further is needed. A more indirect approach may be made through an incision above the hairline and the depression may be elevated by sliding it down beneath the temporal fascia. Impaction is not dependent on the method of elevation. If impaction does not occur, open operation and wire fixation may be necessary.

Fracture-dislocation of the zygoma (Fig. 25) usually follows trauma to the cheek bone because of the prominent position of the zygoma and is often associated with fracture of other bones in the face or jaw. The zygoma itself is usually not fractured but is separated from all of its attachments and crushes the thinner surrounding bones, including the maxilla, with crumpling of the antrum and depression of the orbital border and floor. The effect of dislocating the

Figure 25 Drawing showing the result of fracture-dislocation of the left zygoma and the method of direct bimanual reduction. Heavy zygoma crushing the thin-walled orbital floor and antral wall causes expected comminution, while the main body of the zygoma itself is rarely broken. The possibility of injury to the optic nerve by these sharp fragments can be appreciated as well as damage to the orbit by the upright process of the zygoma. Position of lengthened orbital cavity, leaving the globe to drop, and the resultant diplopia are shown. The end of a Kelly clamp engaging the angle of the zygoma to elevate it into position after entrance through the fracture line in the antral wall into the antrum itself is demonstrated. At this point the fingers of the other hand are placed on the inferior orbital floor and the zygoma is placed in reduction. The comminuted floor and wall are "mulched" into position by a clamp placed on the inside and a hand placed on the outside, then held, until union has occurred, by an iodoform pack impregnated with balsam of Peru accorded into the antrum.

zygoma might be compared to that of placing a marble on an egg and striking the marble with a hammer, the marble representing the zygoma and the egg the surrounding bones. As could be imagined, the marble would be broken if a strong enough blow were used, but crushing of the egg is inevitable.

Diagnosis of a fracture-dislocation of the zygoma is usually easy to establish by palpation, particularly of the inferior orbital border. Swelling may be marked and may

berculosis, Actinomyces and Treponema pallidum.

Periapical abscess is really localized osteomyelitis and usually spreads by the extraction of an acutely abscessed tooth. *Pericoronitis* is soft tissue inflammation around a partially erupted third molar which may progress to osteomyelitis spontaneously or more commonly following extraction performed when the tooth was acutely abscessed.

B

C

Figure 26 A, Severe fracture of nose with soft tissue laceration and contusion as shown in x-ray. Accurate replacement of bony fragments and soft tissue parts avoids secondary operative procedures. B, Result of permanently displaced old fracture of the nose. Secondary dorsal build-up necessary when immediate elevation not done. C, Cut-down of nose results in proper feature balance.

Fractures are the second most common cause of osteomyelitis. In all fractures of the jaw, drainage to the outside should be considered since it is almost impossible for the jaw to break and not lacerate the mucosa if teeth are present. An avenue to the bone for mouth organisms is opened up. Prevention by prophylactic drainage is the best treatment, although reliance is often placed on antibiotic protection.

Cysts are a potential pocket for infection and the avenue for mouth organisms may be via a nonvital tooth root.

Metals, such as arsenic and mercurial compounds, rarely cause necrosis of the jaw.

Thermal necrosis of the jaw may follow caustic destruction of an overlying carcinoma and is usually relatively localized.

Irradiation is not an infrequent cause of osteomyelitis and is distinguished by the intense pain. It usually follows irradiation to carcinoma of the mouth near the bone. Involvement may be widespread with the healing slow and promise of secondary breakdown great.

In the acute stage of osteomyelitis, pain is the prominent symptom and it may be very severe. There may be a history of a recent extraction of an acutely inflamed tooth. Swelling may be diffuse about the face and extend down into the neck. Tenderness is marked and may be over the jaw or generalized over the swollen area. Trismus may be marked. There are also the general signs and symptoms of infection, such as fever and general malaise. X-ray films may show very little in this acute phase other than the cavity left by extraction of the tooth with slight bony erosion. In the chronic stage, there is local reaction to a foreign body and purulent drainage with acute exacerbations accompanied by general reaction. Multiple sinus tracts will be present by now, possibly with an oral fistula. X-ray examination in the chronic stage will show cavities, sequestra and, later, the developing involucrum.

Prevention is the best possible treatment. Though this may be a trite saying, and should be self-evident, prevention is worth while if one patient can be saved from osteomyelitis. Dentists have learned that an acutely inflamed tooth should not be extracted since, instead of allowing for drainage, new avenues for spread are opened up by this procedure. External drainage for fractures of the jaw will reduce the incidence of osteomyelitis.

Antibiotics in large doses are used and

Figure 26 See opposite page for legend.

A

areas of necrosis. Identification of tubercle bacilli is necessary for the final diagnosis. Treatment may be more radical than for other forms of osteomyelitis. Sequestrectomy, excision of involved soft tissue and closure of the wound are done while an adequate streptomycin blood level is being maintained.

Infection of the jaw with *Actinomyces* should be strongly suspected from the history. Typically, a chronically infected lower molar is extracted and three weeks later a painless mass appears over the jaw, which increases in size and becomes painful and inflamed; trismus appears and there is the usual general response to infection. Drainage may be spontaneous and subsidence occurs, but the painful swelling appears recurrently. The typical late picture is that of widespread induration in the face and neck, multiple draining sinuses and scars and the inability to open the mouth. X-ray examination shows osteomyelitis. The diagnosis is established by finding sulfur granules in the drainage, but it may be necessary to open a new pocket to demonstrate them. Microscopic confirmation is advisable. Treatment consists in drainage of the multiple abscesses, x-ray therapy and prolonged systematic usage of antibiotics. Excision of the involved soft tissue may be necessary.

Syphilis involving the jaw bones is rarely seen. The usual involvement is of the hard palate and the supports to the nose. Treatment consists of the usual systemic therapy for syphilis, but later reconstruction and closing of the defects may be necessary.

Ankylosis may be true or false. True ankylosis results from bony union at or near the joint and has been seen following mastoiditis, osteomyelitis elsewhere in the jaw and fracture. Patients have been seen who were unable to open their mouths for years. One or both sides may be involved. When it occurs on one side, the body of the jaw appears more normal on the ankylosed side than it does on the uninvolved side. If any opening is possible, the jaw deviates to the ankylosed side, and the preangular notch is deepened on that side. X-rays may show the extent of damage and union at the joint. Also, involvement of the coronoid should be determined since it has been seen solidly fixed by bony union. A series of coronoid ankylosis alone, resulting from war wounds, has been reported. Treatment of true ankylosis consists in resection of enough bone for a false joint to develop. Bilateral true ankylosis is a particular problem, since for-

ward support of the jaw may be lost and tracheotomy may be necessary. In such instances, the worse side should be operated on first and possibly enough opening may result following unilateral relief. *False ankylosis* is due to scarred bands which prevent the jaw from opening, but it may be difficult to distinguish from bony ankylosis, both may be present to some degree. The scar requires excision and some substitution with a graft or flap is required for relief of false ankylosis. The scar of a neck contracture may produce a type of false ankylosis by pulling on the chin and inducing an anterior dislocation of the jaw, as in Figure 28.

Tumors of the Jaw. Tumors, benign and malignant, which occur in other bones of the body also are found in the jaws. Their treatment is essentially the same as in other locations and further discussion is unnecessary. In addition, there are tumors in the jaw which are peculiar to it owing chiefly to the presence of teeth.

Torus palatinus is an osteoma or exostosis which is more or less symmetrical and is found in the midline of the hard palate. Because of its size, which may affect the speech or prevent the proper fitting of dentures, or irritation, it may require removal. Excision is not difficult, but opening into the floor of the nose should be avoided. *Torus mandibularis* is a similar occurrence of an exostosis inside the lower jaw which may be in the midline or symmetrical on both sides. Removal is usually not required, but it may be necessary to allow for a lower dental plate.

Dental cysts, root cysts or radicular cysts are probably of infectious origin and are seen on x-ray films as a cyst in the bone surrounding a tooth root or a retained root. Cure requires removal of the root and the cyst. The bony defect is allowed to heal from the bottom.

Dentigerous cysts are epithelia lined and contain a tooth bud or unerupted tooth. Bone is eroded as they distend but is not invaded by the cell. They must be completely removed.

Adamantinomas, or ameloblastomas, are tumors which arise from the preameloblasts, or cells which later form the enamel of a tooth. They may be cystic or solid and usually occur as a mixture of solid and cystic elements. X-ray films may show a multilocular arrangement with erosion of the bone by pressure. The more solid the tumor is, the more apt it is to invade bone. This may proceed so far as to make the tumor malign-

Figure 27 Osteomyelitis. The drainage incisions are shown. The cheek was just about to perforate. The second picture was taken two weeks after the first.

have prevented the local progress of the infection to extensive bone necrosis. Their use has also undoubtedly saved lives.

Upper alveolar or maxillary osteomyelitis is much less common than is osteomyelitis in the mandible and occurs most frequently in the region of the incisors, canines or at the tubercles. Infection may spread from the nose or paranasal sinuses in addition to that associated with the teeth. Often the most prominent symptom is periorbital edema. Treatment follows the same principles outlined for osteomyelitis of the mandible.

Gumboil, or alveolar abscess, should be drained by incising the mucosa and gently retracting the periosteum. The tooth can be extracted when the process has subsided.

Once an abscess has developed, it is usually opened externally, otherwise the infection may spread and dissect all the closing muscles of the mouth, including the masseter, internal pterygoid and the temporal. A short collar incision is made through the skin, followed by blunt dissection into the abscess and to the bone, care being taken to make the opening into the masseter space on the outside and into the internal pterygoid space on the inside.

The abscess is evacuated and a light iodoform pack is inserted to be left in place for twenty-four hours to establish the drainage tract.

No cutting of bone is done at this stage.

The jaw sequesters rapidly and to cut into it invites further spread of the osteomyelitis. Spontaneous separation of any fragments is awaited for up to twelve weeks and, during this time, secondary drainage may be necessary. Also, during this time the process changes from an acute to a chronic one and becomes less dangerous.

Maintenance of the arch of the jaw is the most important consideration when osteomyelitis has developed. Conservative management is indicated. Though antibiotics may hasten the development of an involucrum and save lives, the dental arch is a mechanical problem and the principles of handling potential sequestra are the same as those outlined twenty years ago. The involucrum must have formed before sequestra are removed and then they can be gently lifted out. If the jaw is allowed to collapse by radical débridement, it is almost impossible to reconstruct the arch.

Block necrosis of the mandible has been followed by regeneration of an essentially normal arch by conservative management of the sequestra.

Tooth buds in children should be conservatively drained.

Tuberculosis of the jaw is rare and is usually a more indolent process than is osteomyelitis. A large fluctuant area may be present over the jaw with multiple draining sinuses. X-ray examination may show spotty

their own splints. As these grafts may bridge defects and do not simply act as splints while union occurs, they are thought to be true grafts and to persist as such. Obviously, bone-bank nonviable material is not considered as applicable for this permanent bridging of defects as are fresh autografts.

The *soft tissue pocket* into which the graft is to be placed is most important for persistence of the bone graft and union to occur, because success of any deep repair is dependent on primary soft tissue healing over it.

SALIVARY GLANDS AND DUCTS

Trauma. Contusion of a salivary gland, duct or surrounding soft tissue may cause obstruction which is usually of a temporary nature and subsides spontaneously.

Laceration of a salivary gland may be associated with facial lacerations and will be evident on examination. Salivary drainage will be seen and is always looked for in the presence of laceration near the salivary glands. Tears of the parotid or submaxillary salivary glands may result from sharp fragments in jaw fractures. If the laceration is only in the substance of a salivary gland, no special consideration is necessary as healing will take place spontaneously.

Laceration of a duct can result from the same causes and recognition is particularly important as drainage will continue or blockage develop unless it is repaired. All deep lacerations in the region of the salivary ducts should be carefully investigated, as should fractures of the mandible near the submaxillary duct, and immediately repaired. Late scarring may produce obstruction secondarily. Transplantation of the proximal duct opening further back in the mouth may be done instead of anastomosis.

Salivary duct fistula to the outside persist-

ing after injury is very annoying to the patient and requires operative closure, if drainage can be established through it. Changing of the fistula to the inside of the mouth may be necessary if the continuity of the duct cannot be re-established. X-ray treatment to shut off the salivary flow may result in the closure of some small fistulas but cannot be relied on for large ones.

Obstruction to the Salivary System. Obstruction to the flow of saliva from any salivary gland may be due to compression or involvement by scar, infection or tumor or other mass near the duct; infection in the gland or duct; salivary calculus; tumor of the duct or gland, and scar or deformity of the duct. Obstruction without any demonstrable cause is not infrequent.

That obstruction is present is usually obvious as the affected salivary gland becomes enlarged and prominent. The swelling is usually worse on salivary stimulation and may subside to some extent between meals. Swelling may appear suddenly or may develop gradually, depending on the cause. Pain is usually present and in degree related to the amount of swelling and its speed of development. Examination will reveal a swollen tender gland and lack of salivary flow from the orifice of the duct in the mouth, even on tender pressure over the gland or milking of the duct. Purulent material may be draining from the duct. Fever and malaise may be evident, depending on the individual reaction to the particular obstruction. Careful examination of the duct with a lacrimal duct probe may determine the cause of obstruction. X-rays should be taken, but often they are of no or little aid in the diagnosis.

Extrinsic causes of obstruction, such as a constricting scar, infection or tumor, require relief of the primary condition. Care should

Figure 29. Adamantinoma. X-ray appearance indicates the cystic character and expansion of bone.

A

B

split-thickness graft. Watertight integrity of mouth has been restored.

nant by position or extension toward the base of the brain. Adamantinomas have been reported in the long bones. The benign character may change any time and invasion of bone and soft tissue occurs. The change is usually to squamous cell carcinoma, though the original solid adamantinoma looks like a basal cell growth microscopically. Treatment, as long as the tumor is contained in the bone, may be intraoral as for dentigerous cysts. Invasion of the bone requires block excision, which has also been done intraorally and facial scars avoided. Extensive soft tissue involvement requires block removal through a neck approach.

Odontomas arise from odontoblasts. Small tumors of this type may be removed in the same way as are unerupted teeth, but larger ones may require removal of a segment of jaw.

Osteofibromas and *giant cell tumors* are probably the most common benign tumors found in the jaw which do not arise from dental elements, but they are seen only infrequently. In rare instances, giant cell tumors may occur as part of the picture of a parathyroid tumor.

Osteogenic sarcoma is infrequently seen

but is the most common malignant primary jaw tumor. *Metastatic carcinoma*, *erosion or invasion by alveolar carcinoma*, or that arising in *salivary glands* or by secondary invasion from *metastatic lymph nodes*, is of more common occurrence.

Chondrosarcoma usually occurs in the lower jaw about the joint and is perhaps one of the sarcomas most often controlled by operation.

Carcinoma of the jaw does not occur spontaneously, but by secondary invasion from buccal or alveolar carcinoma. There is, however, an exception to the above statement, in that adamantinomas may become malignant and form carcinomas in the jaw itself, the originating epithelial cell coming from the paradental debris left in the jaw following formation of the enamel organ.

Bone Grafts to the Jaw. Bone grafts are necessary to bridge defects in the jaw following loss from any cause. They are often used to promote union where there previously has been failure and to fill out contours. Ribs are most useful for graft material because of their natural shape and iliac crests may be well shaped to fit defects. Solid grafts may be wired in place to become

vary glands are of the same types as those which are found in soft tissue elsewhere in the body, e.g., lymphangioma, angioma and lipoma. Mixed tumors of anlage origin (Fig. 31) are usually thought of as being inherent in salivary glands, but they have been observed elsewhere in the body. Papillary cystadenoma lymphomatosum is found in these salivary glands. One hundred and eighty-seven tumors were removed from the parotid gland over a twelve-year period without evidence of recurrence or paralysis of the facial nerve. One hundred were benign mixed tumors. Papillary cystadenoma lymphomatosum comprised 3.4 per cent; lipoma, 0.6 per cent; angioma, 1.4 per cent; and 5.3 per cent proved to be lymphangioma.

Benign mixed tumors occurring in the salivary glands are thought to be of *anlage origin*, as postulated by Halpert, from nests of embryonal ectoderm which do not imitate salivary gland or distort the gland with growth. Similar tumors occur elsewhere in the body and the relationship between tumor and gland is incidental. Occurrence may be multiple. Eighty-nine per cent are found in the parotid, 10 per cent in the submaxillary and 1 per cent in the sublingual gland. They may be found in persons of any age, most commonly in those between thirty and fifty years. The characteristic microscopic appearance is that of epithelial cells in cords, lumps or stellate arrangement set in a stroma of collagen which may look like car-

tilage and which may be part of the tumor cells themselves.

The diagnosis is made on the history of a painless mass which appears in a salivary gland and slowly increases in size, but unrelated to salivary stimulation. A solid mass can be felt in the gland not attached to the skin. Facial nerve function remains unimpaired regardless of the ultimate size. Sialography usually does not help in making the diagnosis. Removal is recommended as soon as the diagnosis is made. In the parotid gland, the closeness of the facial nerve and its frequent association with the tumor make the problem of complete tumor removal without damaging the nerve worthy of special consideration. Wide exposure to the entire surface of the gland is necessary to remove the tumor safely (Figs. 32 and 33). A direct approach is made to the tumor and the mass is removed completely with careful, minute pressure on all surrounding gland elements, which might contain nerve filaments, before they are cut. Fortunately, the majority of tumors lie over the facial nerve and they can best be removed in the manner just described. If the tumor is beneath the nerve, this will be evident. The major divisions of the facial nerve can be identified and protected from injury by dissecting the tumor from these and smaller fibers. An individual observer of the face is part of the operating team and he reports any movement or twitching of the face as the operation progresses. The skin is carefully closed

Figure 31. Bilateral benign mixed tumors of anlage origin; removed as indicated in Figures 32 and 33 with preservation of the facial nerves.

Figure 30. X-ray appearance of salivary calculi in submaxillary duct.

be exercised in removal of tumors near the salivary ducts.

Infection in a salivary gland or duct is one of the most important causes of obstruction. It may be associated with a calculus and thus should be established at the onset. Obstruction may result from the edema of infection or persist after removal of a stone. Although a single organism may initiate the infection, the usual mouth organisms can be cultured when symptoms begin. Swelling of both submaxillary and parotid glands may be noticed in severely debilitated subjects.

Treatment consists in the administration of systemic antibiotics and salivary stimulants, mouth cleanliness, including care of gum disease and carious teeth, and administration of sedatives or analgesics necessary for general comfort. Carefully probing the duct with a small lacrimal duct probe might reveal the presence of a stone, it is a part of the treatment, allowing draining and at least temporary relief from the swelling. Subsidence is usually fairly rapid unless there is some other fundamental reason for persistence, but recurrences are common and enlargement of the duct orifice may be necessary. Persistent infection in the gland may require its removal. Glandular elements by this time are pretty well destroyed. Use of irradiation to stop salivary secretion is considered in those subjects in whom no cause for the obstruction is demonstrable.

Calculus in the duct or in the gland is the second most common cause of obstruction. The signs and symptoms are those of obstruction and infection is usually present. Careful probing of the duct with a small lacrimal probe will establish the fact that obstruction is present or a grating of the duct on the stone may be heard or felt. X-ray examination may help to determine the position of the stone (Fig. 30), but

superposition of the jaw may prevent visualization. More than one stone is often present. Treatment consists in removal of the stone and relief is usually immediate. Enlargement of the duct orifice may prevent stone formation or permit passage of stones already formed. It may be impossible to remove stones in the gland or those which have migrated into the surrounding area and it may be necessary to remove the affected gland and duct. Antibiotics and salivary stimulants are used.

Tumors arising from the salivary ducts are rare and obstruction is slower than that by stone or infection. Tumors in the gland itself are not usually present.

Scar or deformity of the duct from other causes resulting in obstruction is not uncommon. Scars following passage of a stone or resulting from excessive trauma in their removal are often not of sufficient severity to require operative correction. Repaired lacerations of ducts may be responsible for obstruction after healing is complete. Local revision of the scar may relieve the obstruction or a new opening may be made in the mouth proximal to the blocked area. Deformity of the duct may be due to atresia anywhere in the duct, but the commonest site seems to be at the orifice. The opening may be of sufficient size, but, in persons of any age, slight inflammation in the duct or around the opening into the mouth may cause obstruction to the salivary flow. Repeated careful dilation with a lacrimal probe may suffice, but the orifice may require enlarging.

Obstruction to any salivary gland may occur without any demonstrable cause being found. This may be recurrent. Three light doses of deep irradiation may be sufficient to shut off the gland, but, if not, actual removal may be necessary.

Benign Tumors of the Salivary Glands. Benign tumors occurring in the major sali-

salivary gland tumors will be the most accurate because of the high incidence of a mixture of various types of carcinoma in the same tumor. Tissue resembling adenocarcinoma and squamous cell carcinoma has been seen on the same slide. In addition to these two types of carcinoma, a third, called malignant mixed tumor, is not infrequently seen. Evidence of benign mixed tumor may or may not be found in association with a malignant tumor. Carcinoma may originate as a benign mixed tumor.

Malignant tumors of the parotid gland can be accurately diagnosed by the history of a hard solid mass in the gland which has rapidly increased in size or has paralyzed part or all of the facial nerve, or if there is fixation of the mass to its surroundings or evidence of extension or metastasis. X-ray examination of the chest should be made. Biopsy is only occasionally necessary because of the high degree of accuracy of clinical diagnosis and of the plan of procedure in which the original operation is considered as a biopsy if unsuspected malignant cells are discovered. Frozen sections of those tumors that are difficult to diagnose are not dependable in many instances. Microscopic interpretation is evidently so difficult that if biopsy is necessary, removal of adequate material is worth while. Tissue

obtained by punch biopsy may show a benign tumor but, a few millimeters distant, there may be carcinoma which would be missed. Biopsy, if necessary, has the same surgical requirements as does removal of a benign tumor.

Treatment of malignant parotid tumors may be surgical excision, irradiation, or a combination of both. Interstitial irradiation with radon seeds has been used very successfully to control the malignant tumor locally and the facial nerve is saved if it is not already involved by the carcinoma. Cure of metastatic lesions, when present, requires surgical excision as do areas of potential spread. A radical operation for cure of carcinoma of the parotid includes removal of the entire gland, including the nerve, as indicated, and occasionally the overlying skin and mandible, combined with a complete neck dissection. En bloc excision of the primary tumor and area of lymph spread is possible; excision of the jaw and skin is carried out as necessary.

Malignant tumors of the submaxillary gland require removal of the entire gland and a neck dissection. The tissues can be removed in one block and as much of the mandible and skin is removed as is necessary. X-ray examination of the chest should be made.

Wash the sutures and a pressure dressing is applied to seal the flaps down and insure a minimal scar.

as far as possible leaving a scarless incision. The incision may be continued into the neck for neck dissection when a malignant parotid tumor is present. An endotracheal tube is used to provide an airway when general anesthesia is employed. The entire face is exposed during the operation.

and a comfortable, firm pressure dressing is applied. Healing takes place in five to seven days. The resultant scar is minimal owing to the placement of the original incision.

Papillary cystadenoma lymphomatosum is removed in the same manner as are benign mixed tumors. It recurs less frequently than do the benign mixed tumors.

Lipomas are treated in a similar way as positive diagnosis often cannot be made until the tumor has been exposed.

Growing, solid *hemangiomas* which are found in infants usually do not require a biopsy for diagnosis and are very responsive to irradiation given in small doses. Surgical removal of this type of angioma is unnecessary and invites damage to the facial nerve. *Cavernous angiomas*, or a mixture of large and small vessel angiomas, are evident on examination and are treated by a combination of irradiation, packing and excision.

Lymphangioma is usually seen in infants but may be first noticed in individuals of any age. It occurs as a soft, compressible, painless tumor which is indefinite in outline. Change in character to an acutely swollen tender mass may be due to blood

leak into one of the spaces. The tumor may extend into the mouth or into the neck where it is called *hygroma*. The treatment is the same as that described for lymphangioma occurring in the mouth and it is sufficient to say that complete removal is often not possible or necessary. Making an opening into the area through the usual wide incision, partial excision of the mass and

lined spaces and healing of the space may occur.

Other salivary glands may contain benign tumors. The easiest method for removal of these is usually total excision of the gland and the contained tumor.

Malignant Tumors of the Salivary Glands. Malignant tumors may occur in any salivary gland. The parotid is most frequently the seat of tumors, but the submaxillary tumors are more common. The incidence of malignant tumors of the parotid gland is reported as high as 80 to 90 per cent.

The simplest microscopic classification of

THE NECK

Developmental Anomalies, Tumors, Infections and Wounds of the Neck

By WALTER W. CARROLL, M.D.

WALTER WILLIAM CARROLL, Associate Professor of Surgery at Northwestern University, received his education and surgical training at the University's School of Medicine. He is representative of the young surgeon in practice who devotes a large share of his time to teaching and research upon a wholly voluntary basis. His interest in surgery of the neck is manifested in his contributions to the literature.

DEVELOPMENTAL ANOMALIES OF THE NECK

Early in the course of intrauterine life, the embryo differentiates the anlage of adult neck structures. The jaws and neck are intimately related to the transient branchial arches which appear in the third and fourth weeks. The thyroglossal duct also appears at this time. During the course of the subsequent two to three weeks, these structures lose their identity as they form the more permanent organs of future life. Within the depths of these tissues, the paired jugular lymphatic anlage appears during the six- to eight-week period and primary lymph glands begin to differentiate shortly thereafter during the third month. Characteristic lateral and midline anomalies may result

from slight alterations in these normal embryologic transitions. Defects in fusion or failure of normal oblitative processes results in formation of cysts, sinuses or even fistulae connecting with the pharynx. In the newborn, these may be of such size as seriously to interfere with vital functions. If respiratory or cardiovascular complications are minimal, they may remain only as cosmetic deformities or become the source of repeated episodes of infection.

LATERAL ANOMALIES

The majority of cysts, sinuses and fistulae located in the lateral portion of the neck are the result of faulty development. These lesions are found at any age, but for the most part in the young. While in patients

in some patients drains to the outside in a spontaneous manner. If this occurs, or if the cysts are drained surgically, a permanent sinus tract develops. The cysts are then converted into a sinus with cystlike pocketing above the opening.

These anomalous sinuses and fistulae may present themselves in three variations with respect to surface openings. The tract may be complete, that is, there may be a well-defined external cutaneous opening as well as an internal pharyngeal opening. In such instances the external opening will be found anywhere along the anterior border of the sternocleidomastoid muscle, but most commonly along the lower third. Coursing upward, it is somewhat superficial but penetrates the platysma muscle and enveloping layer of the deep cervical fascia. It passes over the common carotid artery and, remaining anterior to the hypoglossal nerve, it turns medially to pass through the upper portion of the carotid bifurcation area to enter the pharynx at Rosenmüller's pouch (Fig. 1).

The sinus tract may be incomplete in one of two ways. The more common of this type are those in which there is a well-defined external orifice leading into a sinus tract which extends only a short distance into the neck but follows the general path upward as described for the complete fistula. The less common variety is that in which there will be found only an internal opening into the pharynx which connects with a short sinus or flat cyst in the parapharyngeal region near the tonsil. In reality, these latter two types are only sinuses and by definition should not be referred to as fistulae.

Correlation of Embryology and Pathology. It is significant to note that these complete fistulae extend from the tonsillar fossa downward under the angle of the mandible, passing under the midportion of the posterior belly of the digastric muscle, and anterior to the glossopharyngeal and hypoglossal nerves through the upper area of the carotid bifurcation, eventually making their way to the cutaneous surface at some lower point. In an effort to substantiate the theory that these lesions arise from the branchial apparatus rather than from the thymic anlage, Gross points out that the fourth and fifth clefts can be ruled out because the cutaneous openings are always found above the residues of the fourth and fifth clefts. To rule out the third cleft, the site of origin of the "thymic duct," it is mentioned that the tract to be derived from this must course

posteroinferiorly to the glossopharyngeal nerve which runs in the third arch. This appears to be most rare. Further, if a lateral cervical fistula were to develop from the second branchial cleft, it would have to lie between the internal and external carotid arteries and extend into the pharynx only in the area of the base of the tonsil or along the posterior tonsillar pillar. Since this is the common experience, it is concluded that the great majority of congenital fistulae of the neck originate from the second branchial pouch and cleft. The existence of this complete fistula presupposes the breaking through of the embryonic membrane separating the pouch from the cleft. This may come about through an embryonic perforation or postnatal infectious process.

Diagnosis. Branchial cysts most commonly are found at the hyoid level. They tend to produce a superficial bulge which may displace the sternocleidomastoid muscle. They often can be moved slightly by the examiner and, on aspiration, they yield a typical fluid which contains cholesterol crystals. The latter finding may be helpful since some of these contain fluid that bears a striking resemblance to tuberculous exudate. Injection of a radiopaque iodine solution into the cyst sometimes will confirm this differentiation. Branchial cysts are quite smooth-walled and thus will produce a sharp outline as compared with the ragged edges of tuberculous abscesses.

Branchial sinuses and fistulae can be recognized by their characteristic external opening along the anterior border of the

Figure 1. Course and relations of embryonic branchiogenic sinuses. All lateral cysts and sinuses follow this tract.

under fifteen years of age more fistulae and sinuses than cysts will be found, in the age group over fifteen years there will be a predominance of cysts. Of the fistulae which require surgical treatment over half will have been present since birth, the majority of the remainder having appeared before the age of fifteen. On the other hand, cysts are found to arise more commonly as an insidious and painless swelling along the anterior border of the sternocleidomastoid muscle in the second and third decades.

While branchial cleft anomalies are usually thought to be developmental rather than genetic in origin, it is of some interest to mention that recent distribution studies of patients with bilateral defects have demonstrated a "familial tendency," i.e., an inherited tendency which has been transmitted through the male as well as the female.

Embryology. Despite a high degree of consistency in the various locations, appearance and clinical courses of these anomalies, there are divergent views regarding their exact manner of origin. These entities have properly become known as branchial cysts and sinuses, because of the general agreement that those lesions found at or above the level of the hyoid bone arise from the second branchial cleft and pouch. Since some fistulae and sinuses are found below this level along the anterior border of the sternocleidomastoid muscle, some credence has been given to the consideration that their embryologic derivation may be the transient thymopharyngeal duct. The first view seems to be the more reasonable.

During the third week of intrauterine life, the human embryo presents rather clearly a series of five rounded branchial arches on either side of the neck. They are demarcated by four branchial clefts which run parallel to one another somewhat obliquely downward and anteromedially. Each external cleft is matched by an internal evagination called a pharyngeal pouch. Normally, the intervening membrane between each cleft and pouch does not rupture, so there is no communication between the pharyngeal pouch and the branchial cleft.

From the first arch are developed the upper and lower jaw, the malleus and incus, from the second, the lesser cornu of the hyoid, the styloid process and part of the stapes; from the third, the body and greater cornu of the hyoid; from the fourth, the cuneiform cartilages and most of the thy-

roid cartilage, and from the fifth, part of the thyroid cartilage and the corniculate, arytenoid and cricoid cartilages.

The first branchial cleft obliterates except at its dorsal part, which becomes the external auditory meatus. The remaining clefts disappear. Internally, the first pharyngeal pouch gives rise to the eustachian tube and the tympanic cavity; the second may be retained as the tonsillar and suprtonsillar sinus, the third by entodermal outgrowth forms the thymus (by virtue of the thymopharyngeal diverticular duct) and the inferior parathyroids, and the fourth, the superior parathyroids. The tympanic membrane represents the dividing membrane between the first branchial cleft and the first pharyngeal pouch.

Each branchial arch originally is supplied by a main aortic branch, the vessels passing in an anteroposterior direction. These vessels in the first and second arches disappear as main trunks, but the third aortic arch remains as the base of the internal carotid artery. The fourth arch on the right forms the base of the subclavian artery and, on the left, it is transformed into the arch of the aorta.

Pathology and Clinical Course. Branchiogenic cysts and sinuses are characteristically located anterior to the sternocleidomastoid muscle. The cysts usually will be found high in the neck, at or above the level of the hyoid, while the sinus openings may occur at any point from the ear to the suprasternal notch. Both the cysts and sinuses are lined with stratified squamous cells, but some will present columnar or ciliated epithelium. Transitional epithelium has been reported in some cysts located high in the neck. The walls are made up mostly of fibrous tissue interspersed with considerable amounts of lymphoid tissue in the form of scattered follicles. Squamous epithelium has been found by Ward lying deep in the lymphoid tissue and showing some degree of keratinization. This has been interpreted as a probable precancerous change in the same manner as one might consider leukoplakia in the mouth.

The contents of the cysts vary from clear serum to thick sebaceous material, according to the character of the lining. An opaque watery or milky fluid can be expected with squamous epithelium, whereas columnar epithelium produces a thick, sticky, mucoid material. Such cysts will not transilluminate on examination. If they become infected, the fluid content becomes frankly purulent and

which at a later date becomes the hyoid bone. Its distal end corresponds to the region which later becomes the pyramidal lobe of the thyroid. The duct usually atrophies during the sixth week of fetal life, but remnants of an epithelial cord persist for a short time. Rests of cells from this cord may remain anywhere along this tract and later can produce the cysts and sinus tracts found so characteristically in the anterior cervical midline.

Pathology and Clinical Course. Thyroglossal cysts, sinuses and fistulae occur anywhere between the foramen cecum of the tongue and the region just above the suprasternal notch. They are most commonly found about halfway between these extremes, just below the hyoid bone. Some of these cysts may be located superficially while others are much deeper. The majority can be found just beneath the enveloping layer of the cervical fascia, while a few will be deep to the pretracheal fascia. These locations are dependent upon the alternative embryologic levels which the thyroglossal duct may take in relation to the hyoid bone and the fascia which attaches to its anterior and posterior surfaces. An occasional cyst can be found above the hyoid within the substance of the base of the tongue.

These cysts and tracts are lined by stratified squamous, columnar or, occasionally, transitional epithelium. The wall is composed almost entirely of fibrous tissue, the thickness being related to the amount of previous infection. Contrary to the characteristic finding in branchiogenic cysts, these do not have lymphoid elements in the walls. This correlates to some extent with similar findings in the preauricular cysts and sinuses of the branchial group which arise from the first arch and cleft areas. In about 80 per cent of the patients the original lesion is a cyst, while in the remainder it is a sinus or fistula. The anomaly is discovered early in life, more than half being noted from soon after birth up until the patient is ten years of age. Since the lesions produce so few symptoms, there often is delay before patients in the remaining group report for treatment.

Thyroglossal cysts vary from 1 to 5 cm. in diameter, the average being about 2.5 cm. They are smooth, round and well defined. Because of their attachment to the hyoid bone, the cysts move directly with the act of swallowing but cannot be displaced by the examiner. Unless infection occurs,

they are not attached to the skin. If drainage occurs, they immediately become attached to the skin with formation of a permanent sinus tract. Recurrent infection is the rule in such instances, even though the cyst has been surgically drained. Intermittent drainage then becomes an objectionable problem.

Diagnosis. The salient feature in diagnosis of the average thyroglossal cyst consists in the finding of a smooth, well-rounded and well-demarcated mass lying anterior to the hyoid bone, which may transmit light and always moves easily with deglutition. In the absence of any sinus formation, three alternative lesions must be differentiated: submental dermoid inclusion cysts, sebaceous cysts and ectopic thyroid tissue.

Treatment. The majority of thyroglossal duct cysts and sinuses eventually will require surgical excision. The smaller cysts may not seem significant, but the larger ones obviously are disfiguring. Both the large and the small cysts can be the site of bothersome local infection. When the cyst contents become suppurative, the abscess must be incised and drained as a preliminary procedure. After the induration in the surrounding tissue has resolved, the sinus tract and underlying cyst should be completely excised through a generous transverse elliptical incision. The tract or cyst will be found attached to the hyoid bone. In a few instances, there will be no further upward extension, but a considerable number will penetrate the hyoid. To prevent a recurrence, removal of the central portion of the hyoid should be included in the procedure. The persisting tract, or embryologic residue, above this

Figure 3. Diagram showing course and relations of the embryonic thyroglossal duct. Fistulae, cysts or thyroid remnants may involve any portion of this tract.

sternocleidomastoid muscle. The only symptoms may be the annoying continuous or intermittent discharge of mucus. Occasionally, an episode of cellulitis may occur around the tract. Traction on the external opening may demonstrate the typical upward course of the fibrous-walled sinus. In children, x-ray visualization of the sinus tract is apt to suggest less extension than actually exists, but in adults the well-formed tract can be demonstrated by the injection of a suitable radiopaque solution. Under local anesthesia, a purse-string suture can be placed around the external opening to retain the dye, thus facilitating obtaining x-ray films in various projections. If surgery follows this examination immediately, the dye can be permitted to remain in order to add some bulk to the tract for identification during the excision. Demonstration of the internal opening can be accomplished by injection of methylene blue. This should be done about two days before definitive surgery is to be performed, because the dye is apt to diffuse into the tissues about the tract and be the source of confusion. After a couple of days, it is sufficiently fixed to the tract tissues so that their identification can easily be made. In general, this dye is needed only to confirm location of the internal orifice and is not necessary to outline the tract for excision.

Treatment. Branchial cysts are treated en-

tirely by surgical excision. The best approach is by means of a generous transverse incision parallel to the lines of skin cleavage and over the most prominent portion of the cyst. This will permit adequate mobilization of all surfaces, since these cysts often have numerous points of attachment. Particular care should be exercised to avoid any rupture, assuring complete removal of all epithelial elements. If there is a connection with the pharyngeal wall, careful closure of this should be accomplished to prevent fistula formation.

Branchial sinuses and fistulae are best excised through the "stepladder" method developed by Hamilton Bailey, which is simple and practical (Fig. 2). It allows for entire excision, permitting adequate visualization of the critical uppermost parapharyngeal area. When the fistula is complete, the internal opening can be closed by direct suture of the wall or by ligating the tract flush within the pharynx after it has been turned "inside out." The skin closure produces a fine cosmetic result, since all incisions are parallel to the skin folds.

MIDLINE ANOMALIES

For the most part midline cervical cysts and sinuses arise from remnants of the thyroglossal duct. They constitute the great majority of developmental anomalies located in the anterior portion of the neck. A few anteriorly located cysts (sublingual and submental) are classified as dermoid inclusion cysts since they stem from displaced epithelium. All these lesions produce some cosmetic deformity and, in addition, frequently produce considerable degrees of distress from repeated episodes of local infection. The rare teratomas of the neck occasionally present formidable pressure symptoms in the newborn and therefore are significant.

THYROGLOSSAL CYSTS

Embryology. The thyroid anlage arises as a midline diverticulum from the first branchial pouch at a point marked in later life by the foramen cecum on the posterior portion of the dorsum of the tongue. This epithelial evagination is transformed into a stalked vesicle by the time the embryo has reached three weeks of age. It projects downward and backward from its point of origin as a tubular duct (Fig. 3). This thyroglossal duct bifurcates at its distal portion to form the thyroid lobes. During its transitory existence, the duct passes through an area

at a surprising rate and with a considerable degree of pressure, particularly in the newborn.

Pathology. Cystic hygroma consists of a benign multilocular cystic mass which is very thin walled. The contents are serous and straw colored though sometimes they may be blood stained. Often, there is free communication of fluid between the many compartments so that the mass is not tense, but rather of a soft consistency. The cyst walls do not contain many vessels and those present are very small. Obvious lymph tissue or nodes can be found adherent to the cystic mass or as a part of the walls. On opening the specimen, one will be impressed by the gray-white color of the lining endothelium.

Microscopic examination of the hygroma reveals the wall to be made up of simple connective tissue, but of variable thickness and constitution. The youngest cyst will present scanty cellularity and have a myxomatous appearance. The lymphatic infiltrations will be variable. In older cysts the collagen and fibrous components will be greater in proportion to the increased thickness of the wall.

Occasional discovery of atrophied or necrotic muscle, nerve or other connective tissue has been explained by Goetsch as the result of a part of the fundamental growth and extension of the hygromas. It is his view that there are narrow cords of endothelial cells which occur as finger-like projections from the sequestered lymph buds, and that these cords insinuate themselves between muscle bundles, nerves, blood vessels and other structures. At a later time, these cords develop a lumen which is filled with lymph-like fluid and which eventually enlarges to surround the previously mentioned tissues and to include them in the cystic mass.

Clinical Course. Two thirds of these cystic masses will be found at birth, and 90 per cent of them will have developed by the end of the second year of life. Distribution between the sexes is equal. A few more are found on the left side than on the right, the ratio being about 3 to 2. They occur chiefly in the posterior triangle, behind the sternocleidomastoid muscle, and often occupy the whole supraclavicular area. A smaller number will be found in the submaxillary area of the anterior triangle, tending to infiltrate the floor of the mouth.

The size of the mass does not bear any positive relationship to the age of the patient or to the duration of the lesion. Some of the largest specimens have been found in infants only a few weeks old. Since the symptoma-

tology is minimal, there are instances in which many months, or even a year or two, may pass before definite treatment is considered. The cystic mass never is tense as are thyroglossal and branchiogenic cysts. The thin and fragile wall of the early cyst is such that the borders may be poorly defined. The lesion can easily be transillumined in this phase. With the passage of time, some degree of infection may develop and a thicker-walled, more fibrotic cystic mass then develops with more extensive involvement through adhesion to the surrounding parts.

Diagnosis. The characteristic presenting complaint is that of a mass in the neck which produces some disfigurement and occasionally some limitation of motion because of its extremely large size. These cysts tend to lie in a superficial plane, despite the fact that they are known to infiltrate deeply even into the mediastinum. Since they do not interfere with the great vessels, trachea or esophagus, they do not present bothersome obstructive symptoms as a rule.

Considerable variation of opinion exists with regard to the value of roentgen-ray examination in these patients because the full extent of the mass seldom can be determined by this method. Certainly, some of the cavities can be outlined by the instillation of an aqueous iodide solution. This may demonstrate more exactly any displacement of surrounding parts, as well as give further information concerning extension of the hygroma into the mediastinum. Such positive findings often are helpful to the surgeon, but negative results from such examinations should be recognized in advance as meaningless.

Treatment. A good deal of improvement in the surgical treatment of cystic hygroma has taken place in the last two decades, so that this form of therapy now is the one of choice. An expectant attitude once was advised in the hope that spontaneous regression might occur. Although temporary decrease in the size of such a cyst does occur, and even a spontaneous disappearance of the mass may take place, eventually it refills and to such an extent that it may become larger.

Radiation therapy should be mentioned only to point out its ineffectiveness. Both radium as a surface application and roentgenotherapy have been used, but with minimal decrease in the size of the average mass. Suffice it to say that hygromas are radio-resistant.

Injection of sclerosing agents has been

level then can be cored out of the base of the tongue up to the foramen cecum. This type of block dissection, originally suggested by Sistrunk in 1928, reduces recurrence to a minimum. The hyoid bone need not be sutured in the midline, since this defect does not alter subsequent muscle action. The wound is closed primarily for the best healing.

Ectopic thyroid tissue occasionally will be found in the area usually occupied by thyroglossal duct cysts. This should be mentioned only as a warning, because such ectopic tissue may constitute the entire supply of thyroid for the whole body. In such cases, the thyroid mass will be identified as solid reddish-brown tissue rather than a substance of cystic nature. If no thyroid tissue is found beneath the strap muscles, this solid mass can be split in the middle and gently placed to each side of the trachea under the strap muscles without disrupting the blood supply.

DERMOID INCLUSION CYSTS

Submental dermoid inclusion cysts are the result of incomplete union of the first two branchial arch components. If the failure of union is external, the cyst will be more superficial and will be lined with epidermal elements, thus becoming known as a dermoid containing hair and various types of thick fluid. If the failure of union is internal, the cysts will be deeper in the floor of the mouth (sublingual) and may be lined with mucous membrane. The more common origin is faulty obliteration of the first and second clefts (ectoderm), so that the result is a simple inclusion cyst. The second cleft is the offender much more often than the first, the results being epithelial-lined cysts in the aural, submaxillary, sublingual and submental regions. They need not be attached to the overlying skin, as are the usual sebaceous cysts. Since they usually are larger than the latter and contain the mixed product of the sweat and sebaceous glands, the soft cheesy material may present a doughy sensation to the examiner and when found it is characteristic. Treatment is surgical excision.

TERATOMAS OF THE NECK

Teratomas of the neck are of rare occurrence, but when present are quite significant. They usually are noted immediately after birth. They consist of large, cystic, solitary masses in the anterior portion of the neck, often causing various degrees of tracheal obstruction. Their anterior or anterolateral

location often suggests an origin from the thyroid gland, but in most instances this never is confirmed. They tend to be encapsulated and rarely, in patients of this early age, are found to be malignant. From the gross as well as the microscopic standpoint, these teratomas are the same as those found elsewhere in that all types of tissue are found, with cysts and solid material being freely interspersed.

Because of their size, they usually require early resection for relief of tracheal compression. In some instances, operation may have to be performed soon after birth in order to prevent further deterioration from respiratory obstruction or difficulties with swallowing. The prognosis in such children always is grave.

CYSTIC HYGROMA COLLI

Cystic hygroma is a well-recognized clinical entity which presents as an irregular endothelial-lined, fluid-containing tissue mass arising from the embryonic lymphatic buds. This lesion is encountered most often in infants and young children but occasionally is seen in adults. Cystic hygromas have been found in the axilla, chest wall, groin and retroperitoneal tissues, but the cervical location is by far the most common.

Etiology. Prior to the embryologic studies of Sabin, the etiologic explanations for these growths were largely unsubstantiated. It is now appreciated that cystic hygromas occur in those areas of the neck, groin or retroperitoneal spaces in which were previously located two proved embryologic structures, that is, the lymphatic sacs of the neck and the lymphatic sacs of the iliac area. With respect to the cervical area, a capillary plexus is formed along each jugular vein which eventually is cut off from the parent vein. The resultant isolated group of endothelial-lined spaces eventually forms primitive jugular sacs by virtue of dilatation and coalescence of these capillaries. The thoracic duct connects the pelvic and retroperitoneal sacs with the left jugular sac and joins the venous system at the jugular valve. An anomaly of development occurs in a few individuals so that portions of the jugular sacs fail to establish suitable communication but retain the growth factor. In addition, it has been demonstrated that hygroma cysts may extend by growth from membranous sprouts derived from the walls of cystic spaces already present. This type of expansion produces a penetrating cystic growth which permeates surrounding tissue.

Since it has been concluded that "making the diagnosis of malignant versus non-malignant carotid body tumors is a dubious venture" by the pathologist, especially on a frozen section, the clinician can only recall that some of these tumors in the past have proved to be so invasive as to cause death. The remarkably slow rate of growth and the critical nature of the arteries involved may be the factors which confuse the issue. It is best to realize that the actual evidence of malignancy is lower than formerly was thought, but the growth potential of this particular tumor is such that, if given enough time, it acts much as a malignant lesion in the sense that it has the capacity to kill the host.

Carotid body tumors cause no subjective symptoms until they reach from 5 to 6 cm. in size. Prior to this time only the mass in the neck is noted and the average patient reports that it took about five to seven years for the tumor to reach such size. Mild pain may be reported, but severe discomfort does not develop until other signs of nerve invasion have appeared.

External examination usually reveals a deeply situated tumor mass in the region of the carotid bifurcation, but the tumor never is attached to the skin. While these masses cannot be moved in the vertical plane, some will permit lateral displacement. Bimanual examination with one finger in the patient's mouth may outline the mass with considerable accuracy. When these tumors are of the more vascular type, firm squeezing pressure may temporarily reduce their size slightly by removal of some of the blood. Presence of a thrill and bruit can be elicited in a few. There may be a transmitted but not an expansile pulsation over these tumors.

Diagnosis. Diagnosis is made on the history of a unilateral cervical tumor mass of some years' duration. Examination shows it to be in the carotid bifurcation area, as evidenced by its relationship to the two arteries, and by the fact that the mass may be moved only in the lateral plane. Carotid angiography may confirm the diagnosis by findings suggesting an intrinsic defect in the carotid wall. Absolute diagnosis is accomplished by histologic study of either the biopsy material or the excised mass. If the study is made of biopsy material, the pathologist should not be required to rule on the question of malignancy since the diagnosis of carotid body tumor itself is difficult enough.

Treatment. In view of the fact that roent-

genotherapy has proved to be of little if any value, surgical excision remains the only method by which these tumors can be eradicated. In the past, operative mortality has approximated 30 per cent when the internal carotid artery has been ligated under general anesthesia. In addition, among those patients who survived the procedure, numerous central nervous system sequelae have been noted. It is obvious that this is too high a price to pay for the eradication of any neoplasm whose incidence of malignancy has been shown to be less than 10 per cent. On the other hand, Munro has reported that 30 per cent of the patients whose treatment was inadequate died as a direct result of their tumors. When the tumor was removed with preservation of the vessels, only 7.5 per cent of the patients died as a result of the tumor.

It must be concluded that early surgical removal is the treatment of choice in order to prevent a mortality of approximately 30 per cent. With care this can be achieved through the simple expedient of obtaining a plane of dissection in the artery wall between the media and the adventitia. Arterial continuity thus can be preserved, but, if this is impossible, definite efforts should be made immediately to restore arterial continuity by using a temporary arterial by-pass, followed by the insertion of a flexible plastic arterial prosthesis at the end of the procedure.

BRANCHIOGENIC CARCINOMA

The presence of a unilateral enlargement in the side of the neck most frequently is a sign of metastatic cancer. For practical purposes, no other diagnosis in the adult should be considered until this probability has been excluded. In addition to those primary tumors previously mentioned, carcinoma of the lung, breast, kidney, gastrointestinal tract and ovary can metastasize to this region. It is of interest to observe that when all of the primary malignant tumors peculiar to the neck are added up, the sum does not equal the incidence of involvement of cervical lymph nodes by metastatic disease. The term "branchiogenic carcinoma" has been found in medical literature ever since 1882, at which time it was suggested that malignant lesions found in the lateral neck might arise from the vestigia of branchial clefts. Prominent pathologists have refuted the existence of branchiogenic carcinoma as a real entity, pointing out that very few of the reported cases could withstand strict scrutiny. Although the term has been retained,

suggested and occasionally utilized, but this method of treatment is fraught with danger. Even though these thin-walled cysts appear to be ideal for this type of therapy, the complications of infection may be disastrous. On the other hand, sclerosing agents have been used most successfully by Ward, when followed within three to six weeks by surgical excision.

Surgical excision is the treatment of choice. To be curative it must include removal of all the endothelial-lined tissue. With the use of endotracheal anesthesia and extremely careful technique, the entire mass can be dissected from its multiple points of attachment. Some importance should be attached to early removal of these growths because, even though they are thin-walled at that time, they are more likely to be better confined to predictable fascial planes than they will later. Older growths tend to be more invasive and adhesive in character. This matter of delay may convert a relatively simple procedure into a long and hazardous operation. These wounds should be closed with suction drainage.

PRIMARY TUMORS OF THE NECK

When one considers the diagnostic possibilities presented by a unilateral cervical mass in the adult patient, on the basis of chance alone the best explanation usually is that it represents *metastatic carcinoma* from the oral cavity, the laryngopharyngeal area or the thyroid gland. Tuberculosis, sarcoidosis and malignant lymphoma represent other possibilities. If all of these can be excluded, efforts then can more logically be made to identify the mass as one of the less common primary cervical tumors. After branchial cysts and salivary gland tumors are eliminated from consideration, specific soft-tissue tumors such as lipoma, neurofibroma and fibrosarcoma may enter into the clinical estimate. In such a differentiation, carotid body tumors and aneurysms should be included for the sake of thoroughness. Because these various lesions present such difficulties regarding diagnosis, it is not unusual that the real identity is not established until the mass in question has been surgically exposed and an adequate biopsy study made.

CAROTID BODY TUMORS

Although fewer than 400 carotid body tumors have been reported in the medical literature, this lesion always is a matter of diagnostic and therapeutic importance when

considering lateral neck tumors. Full appreciation of all aspects of these lesions is most desirable for the best therapeutic results because the integrity of the internal carotid artery is directly involved in the surgical excision. Definitive handling of the carotid artery has much to do with the post-operative course and, for this reason, this entity presents a real challenge when discovered.

Embryology. The carotid body is a small, ovoid, irregular mass of pinkish-tan or gray tissue located within the bifurcation of the common carotid artery. At one time it was thought to be related to the so-called chromaffin system, but this does not seem to be the case since it actually is one of a group of discrete tissue masses found near ganglia of the cranial nerves or branchial arch arteries.

These "organs" and the tumors they produce are histologically similar. Though these tumors are recognized as paragangliomas, the term chemodectoma has been used more frequently since first introduced in 1950. They do not give a true chromaffin reaction, contain no epinephrine and do not secrete a hormone. The nerve supply of these bodies is multiple, but mostly sensory; the carotid body, for example, being supplied by the glossopharyngeal nerve. These bodies have been described near the jugular bulb, the ganglion nodosum of the vagus nerve, the innominate artery, the tympanic membrane and the carotid bifurcation. The carotid body, in particular, is known to arise within the adventitial layer of the carotid artery early in embryological development. Although it grows outward from this point as a discrete mass, it never loses this intimate anatomic relationship. In order to excise such a mass, dissection between the media and the outer adventitia is necessary.

Pathology and Clinical Features. Carotid body tumors are noted for their slow rate of growth. Estimation of malignancy from the histologic appearance has been difficult since mitotic figures are exceedingly rare in these tumors. They show a remarkable tendency to reproduce the normal architecture of the carotid body. Although they may vary from an epithelium-like appearance to that of an angioma-like type, the fundamental pattern of tissue origin can best be discovered by the use of reticulum silver-impregnation stains. The majority of them are somewhat adherent to their surroundings, especially to the arterial wall, but the latter point is of embryologic and not neoplastic significance.

For example, a peritonsillar infection can spread directly into the pharyngomavillary space, or, more commonly, the submaxillary space will present a complication of dental infection without any break in mandibular continuity. In addition to these, there is a small group of infections which are secondary to a great variety of open and closed injuries in or about the mouth and neck.

Applied Anatomy. Cervical fascia. The cervical fascia commonly is described as consisting of a superficial and a deep layer. Such a division does exist, but the deep layer is much more complicated and important than such a simple classification would suggest.

The superficial cervical fascia consists of a layer of loose connective tissue located immediately superficial to the platysma muscle over the anterolateral aspects of the neck. It is the *tela subcutanea* which gives support to the skin and which carries a generous supply of nerves, vessels, fat and some muscle. The platysma is intimately attached to it. The superficial fascia encircles the neck as a single layer maintaining the same relationship to the skin throughout its distribution.

Immediately beneath the platysma, the deep layer of cervical fascia is clearly defined (Fig. 4). The outermost (anterior) layer is an enveloping layer, surrounding the large neck muscles so as to invest and hold them together. In the posterior half of the neck, the deep fascia functions entirely to support the heavy musculature, whereas in the anterior half (musculovisceral compartment), it consists of a number of layers, some ensheathing the long muscles, some covering the viscera and the deepest muscles lying over the vertebrae.

As the enveloping layer of the deep cervical fascia extends upward, it attaches anteriorly to the hyoid bone and, after splitting, it attaches to and extends upward over both surfaces of the mandible. It reaches inferiorly to the clavicle and sternum, attaching to the anterior and posterior surfaces to form in the midline the space of Burns. As it extends laterally, it divides to enclose the sternocleidomastoid muscle, crosses the posterior triangle and invests the trapezius. It continues around dorsalward to attach to the spines of the cervical vertebrae.

The middle layer of the deep cervical fascia is also known as the pretracheal fascia.

Figure 4. Deep layers of cervical fascia. Direct access to mediastinal area from upper visceral space is evident.

it seems likely that few examples will be substantiated in the future.

Diagnosis. In order to make the diagnosis of branchiogenic carcinoma the following criteria are necessary: (1) the tumor must be located along a line drawn anterior to the ear, which passes downward along the anterior border of the sternocleidomastoid muscle, (2) the histologic appearance of the tumor must suggest origin from epidermal branchial vestigia, (3) the tumor should demonstrate some relationship to a cyst or sinus tract which might be considered branchial in origin, (4) after removal of the tumor, the patient must survive five years without the development of any other primary malignant lesion which could possibly have produced, by metastasis, the previously excised lesion.

Treatment. If no other primary lesion can be found and the unilateral neck mass is reported as "epidermoid carcinoma," it might be well to defer surgery in the interests of prudence. Radiation can be used for temporary control of the suspect metastatic lesion while sufficient time passes to permit further exploration for the primary lesion. In a few patients, a complete neck dissection may be indicated if the presenting mass is quite large or if the mass proves to be radioresistant.

DEEP CERVICAL INFECTIONS

While not so common in the present practice of surgery, deep cervical infections once were the cause of considerable morbidity and in the neglected state carried an unusually high mortality. Abscesses are particularly prone to occur in the deeper layers of the neck because the deeply situated lymphatics receive drainage of infected material from the oropharynx and upper respiratory passages. Such infections are not only deep in location but also in origin, since the source of infection may be the pharynx, dental structures, temporal bone, salivary glands, the esophagus and respiratory passages. The majority of the abscesses arise from dental infection or from infected tonsils. Continued improvement in the care of the teeth and over-all oral hygiene combined with earlier correction of throat infections have done much to diminish these very troublesome and serious infections.

While, for many reasons, deep cervical abscesses previously were accompanied by a high mortality rate, one of the most significant reasons was the difficulty in accurate localization of the infection because of fail-

ure to appreciate the important relationships of the deep cervical fascia. Even though today we possess a chemotherapeutic and antibiotic armamentarium of considerable potency, early drainage of retained purulent exudate still is required for prompt recovery. The application of the principles of early surgical drainage occasionally is necessary in deep cervical infections and adequacy of such drainage often is dependent upon knowledge of these deep anatomic relationships.

The universal recognition of the importance of fascial planes in the diagnosis and treatment of neck infection has been a relatively recent development. The fascial planes of the neck form well-defined compartments and potential spaces. Infection confined within these compartments may be so hidden that the diagnosis of the presence of an abscess may often be seriously delayed. Extension into the mediastinum may take place while the patient is being observed. Moreover, cardiorespiratory complications may intervene before appropriate drainage has been instituted. Early diagnosis and appropriate treatment often are delayed because the signs usually associated with the accumulation of pus elsewhere in the body may not be manifest when there is a purulent pocket in the deeper structures of the neck.

Etiology. Almost all known organisms have at some time or other been cultured from deep cervical abscesses. The great majority of these infections are due to some strain of streptococci, the latter frequently being obtained in a pure culture. It is not unusual to find a mixed infection, especially with both aerobic and anaerobic variants. While the fusospirochetal organisms of Vincent may be found in both the oral source and the abscess cavity, the blood stream invader may be only the hemolytic streptococcus. Accurate identification of these organisms is important from the therapeutic standpoint because specific sensitivities can be determined to assure the correct choice of antibiotic or chemotherapeutic agent.

Not only is the organism significant, but so are the portal of entrance of the bacterial invaders and the manner in which the infection has developed. Two mechanisms may be at work in the pathogenesis of these infections, that is, there is the possibility of contiguous spread of the infection by direct extension or embolic spread may occur through the lymphatics to the collecting lymph nodes within certain compartments.

over the lower portion of the body of the mandible just posterior to the facial vessels as they lie in relationship to the anterior border of the masseter muscles. The muscle fibers can be divided by blunt dissection and an appropriate soft rubber drain inserted into the pocket. The superior extension of this cavity should be identified, since the temporal extension of this compartment may also require drainage near the zygoma.

PAROTID SPACE. This space contains only the parotid salivary gland, a few significant lymph nodes, a major portion of the facial nerve and numerous vessels. The fascia which invests the masseter muscle thickens considerably at its posterior border and splits to surround the parotid gland. This thick parotid-masseteric fascia is firmly attached to the investing layer of the deep cervical fascia which covers the sternocleidomastoid muscle and, as a result, the gland is completely surrounded by heavy fascia except medially where the parotid tends to become retromandibular. At this point, the deeper layer of the fascia extends toward the pharynx in the region between the styloid process and the internal pterygoid muscle. This lack of covering permits free connection with the retropharyngeal and the pharyngomaxillary spaces at this point.

Infection originating within this space usually is directly related to the salivary gland itself. If it becomes secondarily involved from masticator or pharyngomaxillary space infection, the abscess can be drained by a small vertical incision made over the most prominent, dependent portion of the swollen gland. The thick capsule must be opened transversely to avoid injury to the facial nerve. More than one area may require incision. The gland then can be spread by blunt dissection to obtain drainage.

THE RETROPHARYNGEAL SPACE. The retropharyngeal space is that area found between the prevertebral fascia and the posterior wall of the pharynx. It contains rather loose connective tissue and a few lymph nodes. Inferiorly this space is in direct contact with the mediastinum.

Retropharyngeal abscess most commonly is found in early childhood. At least two well-defined lymph nodes are located in this space at about the level of the second cervical vertebra. Infection in the nose, nasal sinuses or nasopharynx may spread to these nodes or infection may arise within the adenoid region of the posterior nasopharynx and thus extend directly into this area. This may easily become a serious infection since

it lies upon the prevertebral fascia and thus it may extend downward into the mediastinum or laterally into the pharyngomaxillary space and eventually may involve the sheath of the great vessels. In neglected patients, this retropharyngeal swelling may protrude so far down the posterior pharyngeal wall as to involve eventually the larynx and complicate respiration.

The symptoms may begin with fever and a cough and examination may not reveal the indistinct boggy swelling of the posterior pharyngeal wall. Dysphagia and dyspnea develop later. Lateral roentgenograms of the cervical spine area may be helpful in making the diagnosis inasmuch as the soft-tissue swelling displacing the pharynx forward may thus be identified. This abscess should be incised and drained orally before it extends into the lateral cervical region. It is most important in doing this to keep the patient's head low and to use suction to facilitate the immediate drainage.

THE PHARYNGOMAXILLARY SPACE. This is a cone-shaped potential space whose base is in relation to the skull around the jugular foramen and whose apex is at the greater cornu of the hyoid bone. Medially it borders upon the superior constrictor of the pharynx and the tonsillar fossa. The posterior portion is in direct relationship with the retropharyngeal space, the prevertebral fascia actually forming its posterior border. The lateral surface anteriorly is in relation to the internal pterygoid muscle while, more posteriorly, it faces the retromandibular portion of the parotid gland which is not covered by fascia. At this level, as well as below the parotid, the space is in direct contact with the carotid sheath and its contained vessels.

There was a time when infections in this space accounted for over half of the deep infections of the neck, but this number has been greatly reduced in the last decade owing to better control of infection in the usual portals of entrance. Because of its position, this space may be infected from the tonsillar fossa and peritonsillar region, over half of these infections coming from this source. It has been said that every peritonsillar infection is a potential pharyngomaxillary space infection. Less common sources are mastoid infection, infected retropharyngeal nodes, molar teeth and invasion from the parotid and submaxillary spaces. The intimate relationship of the vessels which traverse this compartment is of extreme importance.

Purulent exudate in the pharyngomaxillary

Figure 5 Cut-away diagram to show intimate relationships of fascial spaces in parapharyngeal regions.

It invests the sternohyoid, sternothyroid, thyrohyoid and omohyoid muscles. These split layers fuse laterally and attach to the carotid sheath for firm anchorage. This middle layer attaches superiorly to the hyoid and inferiorly to the posterior surface of the sternum and clavicle, fusing with the enveloping layer of the deep fascia.

The visceral layer of the deep cervical fascia encloses the hypopharynx, esophagus, trachea and thyroid gland. Known as the buccopharyngeal fascia, it covers and supports the outer wall of the pharyngoesophageal region, especially the constrictor musculature. The thyroid is covered by this layer by virtue of its embryologic descent through it, as it moved from the midline region to take up a position lateral to the trachea. This visceral fascial layer forms a definite compartment between the middle layer and the firm prevertebral fascia. It extends from the base of the skull to the thoracic mediastinum.

The prevertebral fascia is the deepest (posterior) layer of the cervical fascia and as such covers the bodies of the cervical vertebrae, the longus colli and the scalene muscles in the posterolateral neck area.

Fascial spaces (Fig. 5). THE MASTICATOR SPACE. The masticator, or submasseteric, space includes the area which contains the masseter, temporal and both pterygoid muscles and all the associated vessels and nerves. This compartment is the result of the

upward splitting of the outer layer of the deep fascia as the latter comes into relation with the mandible. While this space is not primarily cervical in location, it has a direct bearing upon the differential considerations of a deep cervical abscess.

Infection may reach the masticator space by direct extension from the second and, especially, the third lower molar teeth. Occasionally, this region may become indirectly involved by infection from the buccal area anterior to the body of the mandible, from the floor of the mouth or from the parapharyngeal region. Pain in the region of the masseter muscle with some swelling and tenderness accompanied by evident trismus indicates infection in the masticator space. An appropriate dental evaluation is necessary to confirm this diagnosis. Owing to the severe trismus, the patient may be unable to cooperate so that examination may be limited to a roentgenogram of the jaw. A typical area of radiotranslucency will confirm the source of the infection as dental. If left untreated, this type of infection will often spread to the submaxillary compartment or posteromedially into the pharyngomaxillary space. Although accompanying cellulitis will be noted over the angle of the jaw area, a direct extension of the infection posteriorly into the parotid compartment is quite unlikely owing to the thick fascial demarcation. Drainage of this space is accomplished by a small transverse incision

one or both sides of the midline. This differential characteristic is very important since only this latter type of infection carries with it any significant morbidity. When the objective findings of inflammatory involvement are such as to make the diagnosis of Ludwig's angina, early surgical drainage is required, while with the other infections some degree of temporization may be permitted.

The portal of entry of this infection may be a lesion anywhere about the tongue, floor of the mouth and teeth of the lower jaw. The role of dental infection is increasing and is reported to be as high as 90 per cent in some series. The infection may arise either by lymphatic spread or by contiguous extension from infection in the floor of the mouth. In either manner, the sublingual and submaxillary compartments eventually both become involved. The end result is the development of diffuse, edematous and rapidly spreading cellulitis beneath the outer layer of the deep cervical fascia.

Owing to the restraining capacity of the deep cervical fascia, and to a lesser extent of the mylohyoid muscle, inflammatory swelling within the submaxillary and sublingual compartments pushes the tongue upward and backward within the confines of the oral cavity. The patient will have difficulty with speech as well as swallowing. The infection eventually may cause obstruction of the respiratory passages. In addition, a certain number of patients will die from pulmonary infection because of extension if appropriate antibiotics are not used.

The usual clinical history of typical Ludwig's angina is that, following a dental extraction or known dental infection, a painful swelling develops in the floor of the mouth, over a period of two to four days, accompanied by gradual appearance of trismus. Examination of the floor of the mouth, when possible, reveals considerable edema, induration and tenderness. The tongue may be so markedly swollen as to protrude between the teeth and press upon the palate. The submaxillary compartment involvement is manifest by the tense, brawny, tender swelling in the suprahyoid region. This swelling may be either unilateral or involve the entire suprahyoid region on both sides of the midline.

Since the development of chemotherapy and antibiotic therapy, not only has the incidence of this infection been greatly reduced, but also its mortality. In the fully developed case, respiratory obstruction still

remains the most feared complication despite these advances.

One should not wait for fluctuation as a sign of localization or it may be too late. The phlegmonous exudate always is quite deep, tends to expand and hardly ever is purulent. It is possible in some subjects to abort the process by adequate drainage of a primary intraoral source, either through the mouth or through the submaxillary fossa as indicated. In the neglected individual, the need for maintenance of a satisfactory airway may take priority over plans for definitive drainage. Early tracheotomy under such circumstances will assure improved respiratory exchange so that the necessary drainage of the infection then may be accomplished with greater safety. Drainage is accomplished through a generous, transverse, curving incision below and parallel to the outline of the under surface of the body of the mandible. The deep cervical fascia and the mylohyoid muscle are cleanly divided in order to open widely the submaxillary and sublingual compartments.

The essentials of successful treatment are the recognition of the need for tracheotomy and the value of early drainage of both the sublingual and submaxillary compartments. General anesthesia is not to be feared if

Figure 7. Semidiagrammatic sketch showing the location of infection in Ludwig's angina above or below the geniohyoid muscle. Note the boxlike compartment filled by the tongue and adjacent structures and the ease with which inflammation may extend to the region of the larynx.

Figure 6 Semidiagrammatic sketch showing the diaphragm formed by the structures in the floor of the mouth.

fossa may cause the lateral pharyngeal wall to bulge inward. Such change in contour may be mistaken for a simple peritonsillar abscess, but careful inspection will reveal that there is very little swelling of the tonsils themselves. The intimate relationship of the infection to the internal pterygoid muscle and the pterygomandibular ligament frequently results in trismus as an early sign. There also may be some swelling of the parotid gland because of involvement of the exposed retromandibular portion which is not covered by fascia and lies in direct relationship with the lateral aspect of the fossa. These three findings, internal pharyngeal swelling, trismus and parotid swelling, are indicative of deep infection within the pharyngomaxillary space. Early diagnosis is of great importance because, if undetected, these infections may lead to serious deep jugular phlebitis.

Drainage of this space can be accomplished by a generous transverse incision in the lower submaxillary region anterior to the border of the sternocleidomastoid muscle. After the lower portion of the facial vein is divided, the submaxillary gland is elevated. To gain access to the latter, the outer layer of the deep fascia must be cleanly incised just above the level of the hyoid. Blunt dissection in the direction of the angle of the jaw and toward the styloid process deep to the mastoid tip will result in a free flow of pus as the pharyngomaxillary space is reached. Insertion of a soft rubber drain completes the procedure.

THE SUBMANDIBULAR SPACE. This is rather a large space located immediately beneath the body of the mandible. It is outlined by the peripheral borders of the submental and

submaxillary triangles and its depth consists of all the tissues lying between the mucous membrane of the floor of the mouth and the outer layer of the deep cervical fascia (Fig. 6). The submandibular space contains the submaxillary and sublingual salivary glands, numerous related lymph nodes and the hypoglossal and lingual nerves and vessels. The anterior belly of the digastric, the mylohyoid, the geniohyoid and the genioglossus muscles add structure to the space.

It should be appreciated that there are three salient compartments within the submandibular space owing to the diaphragm-like arrangement produced by the mylohyoid muscle. The deepest compartment and actual floor of the mouth is the sublingual space. It contains those structures which lie superior to the mylohyoid and extends from the hyoid bone to the mandible. It connects at the midline with the contralateral sublingual space and with the ipsilateral submaxillary compartment by virtue of the course of the submaxillary salivary gland at the lateral edge of the mylohyoid. The submaxillary compartment contains the submaxillary gland and intimately related lymph nodes. It communicates posteromedially with the pharyngomaxillary and retropharyngeal spaces and thus indirectly with the mediastinum. The third, or submental, compartment consists of the superficial area between the median raphe and the submaxillary border deep to the outer layer of the deep cervical fascia but superficial to the mylohyoid muscle.

Infections in the submandibular spaces may vary from mild cellulitis to fatal phlegmon (Ludwig's angina). Since the different compartments of this space may participate in these infectious processes in varying degree, the anatomic relationships of the area must always be kept in mind (Fig. 7). While the right and left halves of this area may become confluent in the midline when serious infection is present, it is the deep and superficial sections of each half that must be separately evaluated. This is of specific importance in order that a correct diagnosis of Ludwig's infection be made in the event that it should occur. A submental abscess, submaxillary adenitis, cellulitis of the submaxillary gland or an infection limited to the floor of the mouth (sublingual) can be identified rather easily when this anatomic subdivision is kept in mind. On the other hand, a typical Ludwig's infection involves all three compartments, the sublingual, submaxillary and submental, on either

Superficial Wounds. Except for hemorrhage, superficial lacerations of the neck present no problems which differ from those in wounds of similar depth and extent found in other parts of the body. The external and anterior jugular veins, which are located immediately deep to the platysma muscle layer, may produce a startling amount of bleeding when divided. If the neck wound is uncomplicated by other injuries, appropriate first-aid care should be a simple but effective compression dressing until the patient can be transported to a point at which definitive surgical débridement and repair can be accomplished. The struggling behavior of an uncooperative or apprehensive patient will serve to increase the venous back pressure in the jugular system sufficiently to reactivate the venous bleeding to a distressing degree. Since some of this blood comes from the central side of the lacerated vein, a portion of this hemorrhage can be prevented by elevating the head 45 degrees during transportation.

Deep Wounds. Wounds which penetrate the outer, or enveloping, layer of the deep cervical fascia usually are of considerable significance. The deep fascia surrounds the vascular and visceral compartments of the anterior neck in such a manner as to retain any extravasated blood or exudate. The major complications, therefore, from such injuries are hemorrhage, both internal and external, and respiratory obstruction of varying degree and infection. Each and all of these complications can result from severe blunt injuries as well as from wounds by sharp knives and penetrating bullets. A few significant nerve injuries also may occur with penetrating wounds.

A severe contusion on the side of the neck, such as that sustained in boxing when the chin is not flexed to protect the soft parts, may be very harmful. Varying degrees of damage to the wall of the larynx and trachea, as well as deep hematoma formation from ruptured veins, may result. Respiratory difficulties secondary to submucosal hemorrhage, and later edema, may first present as expectoration of blood-tinged sputum, hoarseness, dyspnea or even labored breathing with cyanosis. Severe respiratory difficulty may result from the pressure of a large expanding hematoma before it has been decompressed.

The most common incised wound of the neck often is reported to be that inflicted in attempted suicide. This wound usually is made by the right hand and so will extend

more into the left than the right side of the neck. It may be located above the hyoid bone since the chin probably was extended upward. A deep wound at this level may reach the pharynx and even injure the epiglottis. At a lower level, the trachea may be severed by a similar transverse wound producing profuse bleeding from the anterior jugular veins as well as from the thyroid gland. It is quite possible that the large vessels of the carotid sheath will be protected by the sternocleidomastoid muscle or by virtue of their posterior position, as compared with those of the injured trachea and thyroid gland.

Anterior and anterolateral knife wounds from an assailant, commonly described as "cutthroat," present the immediate dangers of severe hemorrhage and asphyxia. Deep penetrating or puncture wounds of the neck by knife or missile often are rapidly fatal, either as a result of immediate arterial hemorrhage or from extravasation of blood causing early respiratory obstruction by pressure. Hemorrhage may stop when the blood pressure falls to shock level, only to begin again when the patient strains or struggles or when the wound is manipulated. Sudden asphyxia may result from tracheal division, through either retraction of the cut edges or infolding of a part, or by inspiration of a clot of blood into the larynx or trachea. Division of the vagus or recurrent laryngeal nerve in the depths of such wounds causes further respiratory embarrassment through paralysis of the corresponding vocal cord.

Stab wounds in the supraclavicular region or injuries accompanied by forcible depression of the shoulder may result in severe and sometimes permanent damage to the brachial plexus by severance or by stretching. These lateral, incised wounds of the neck occur chiefly in fights or in attempted homicide. They often are followed by severe hemorrhage and, occasionally, by the late development of arteriovenous fistulae. When the supraclavicular space is involved, the subclavian veins and their branches and the thoracic duct and the lung may be injured. The possibility of a complicating pneumothorax or a delayed chylothorax must be kept in mind.

Bullet wounds, as well as the lacerations of war and civil life, are prone to infection. The neck is filled with numerous lymphatics, blood vessels, nerves, viscera and muscles. Some of the neck viscera are hollow and, if perforated, predispose to infection of the

Pentothal sodium is utilized, provided the trachea is first exposed for purposes of tracheotomy, if needed, or provided a preliminary tracheotomy already has been accomplished.

THE CAROTID SHEATH This space contains the great vessels of the neck and, in its more superior area, some of the emerging cranial nerves. It gives off fascial connections to the parotid, submandibular and pharyngomaxillary spaces. This relationship has been likened to a trifolium, the stem of which is the carotid sheath. The arterial and venous branches leave the sheath to enter these compartments invested with the fascia that composes the sheath and which is in direct continuity with the retentive and supportive layers of the deep cervical fascia. Inflammatory interrelationships between these spaces and the carotid sheath thus are quite real and often produce serious complications by virtue of such extension.

Because of its anatomic location, the carotid sheath can readily be infected from the parotid, submaxillary, retropharyngeal and, most commonly, from the pharyngomaxillary space abscesses. It often has been pointed out that local signs are of little value in estimating the possibility of a carotid sheath infection or jugular phlebitis. The swelling and local tenderness in the region of the vessels usually arise from related jugular nodes involved by the prime infection. The only reliable data are those suggestive of severe sepsis: chills and fever, spiking temperature, leukocytosis and positive blood culture. Vigorous antibiotic therapy must be maintained. The importance of penicillin in particular should be stressed. Since an underlying deep abscess is the usual cause of carotid sheath infections, one must not forget the need for surgical drainage if the pocket can be found. Ligation of the deep jugular vein and drainage of the hidden deep abscess may quickly solve the problem.

VISCERAL SPACE INFECTIONS

Trauma from food, from foreign bodies and from instrumentation may result in infection developing within the bounds of the pretracheal fascia, below the level of the superior constrictor muscle. This same space may be involved secondarily by extension from the prevertebral area, or the pharyngomaxillary fossa. Wounds and injuries of the neck also may result in infection along this enveloping fascia. Compound lacerations of the larynx, trachea or esophagus or tears

and lacerations of the cartilage from blunt blows in the neck can be followed by this type of infection.

Visceral space infections always are serious, especially those following esophageal perforation. Mediastinitis is an almost immediate development, occurring within one to four days, before the usual protective barriers can be established by nature. Subcutaneous emphysema is diagnostic of the perforation and can be established either by the characteristic crepitus on physical examination or by roentgenograms. Soft tissue films may demonstrate air under the skin, in the anterior mediastinum or in the retropharyngeal space, under these circumstances. When appropriate early treatment has been omitted, the more fully developed infection will present signs and symptoms characteristic of the viscera involved. Dysphagia may occur when the infection borders upon the constrictors, while alterations in voice tone follow laryngeal edema. Dyspnea may result from either laryngeal obstruction or bronchopneumonia. A sustained febrile course will indicate the severity of the mediastinitis.

Once the presence of subcutaneous emphysema has been established, the treatment of choice for perforative infection of the visceral space is immediate surgical decompression. The deep fascia should be opened widely and the area drained to prevent further extension downward into the mediastinum. If visceral space infection is of the secondary type, treatment is aimed at correction of the source. This may mean simple intraoral drainage of a peritonsillar abscess or exploration and drainage of the pharyngomaxillary space. If obstructive dyspnea is present, a temporary tracheotomy may be required.

WOUNDS OF THE NECK

Injuries to the soft parts of the neck occur somewhat less often than might be expected in view of the extent of their surface in relation to other parts of the body. A portion of the anterior neck often is protected by a flexed jaw or raised shoulder. While such maneuvers often prevent or diminish the force of a blunt injury, they may compound or multiply the number of structures injured in instances of penetrating injuries. For example, fracture of the jaw is a common accompaniment of the deep neck wound. A stab wound at the base of the neck often involves the great vessels of the upper chest and even the heart.

stage if respiratory obstruction is present. Atropine will help to diminish the bronchial secretions, but suction through the tracheotomy opening may be necessary to accomplish an adequate bronchial toilet.

After the general condition of the patient has improved, endoscopic and roentgen-ray examination can be carried out with more care, in order to determine more fully the extent of the injury and to detect the presence of any hidden foreign bodies. If multiple injuries are present, all must be properly assessed and therapeutic priority established. With this information at hand, the wounds then can be repaired.

A general anesthetic should be administered, either by an endotracheal tube or in conjunction with the tracheotomy. Selection of the anesthetic for the patient with a serious neck injury is very important because a high oxygen content is absolutely essential. Although local anesthesia may be used for many elective surgical procedures in the neck, it is not suitable for these patients.

Following appropriate skin cleansing, the packing is removed from the depths of the wound. This is replaced by more specific pressure and each vessel is carefully ligated as fresh bleeding recurs. In knife or bullet wounds, a generous extension of the wound ordinarily will be necessary to obtain satisfactory exposure and control of all bleeding points. Bleeding from large veins may be more troublesome to control than that from arteries, because vein walls are so fragile that they tear easily when handled. Ligation of a large vein requires good exposure and gentle technique. Debridement of devitalized tissue and removal of all foreign bodies are done as indicated. Clots are removed and the wound generously irrigated with saline solution.

While major veins in the neck can be interrupted without fear of central complications, every effort should be made to restore vascular continuity when the carotid artery has been injured. Ligation of the common carotid artery involves the risk of hemiplegia or fatality when it is performed under general anesthesia and in the presence of shock. Suture of lacerations of the carotid wall or end-to-end anastomosis should be performed whenever possible. When large defects are present, arterial homografts or flexible plastic substitutes have proved to be successful on a few occasions.

A complete anatomic survey then is necessary in order to identify lacerations in the viscera. Small defects in the trachea can be

sutured and covered with near-by thyroid or muscle. Sometimes, a two-layered closure of the pharynx can be obtained if the surrounding tissues are properly mobilized. Major defects in the larger muscles can be closed by loose suture. When viscera have been perforated, no attempt should be made to close the deep cervical fascia. A small, thin, rubber drain can be permitted to come to the outside from the visceral space, but it never should be left in direct contact with the sutured wall. These maneuvers serve to decompress the retropharyngeal and visceral spaces and therefore diminish the potential of mediastinal infection. Gentle suction drainage will facilitate both wound healing and postoperative nursing care.

In the course of immediate after-care all patients with deep neck wounds should receive penicillin or other appropriate antibiotics in order to reduce the likelihood of infection. Nutrition and fluid balance can be maintained by the early and continuous use of small nasogastric tubes. The late complications of persistent orocutaneous fistula, carotid aneurysm and various arteriovenous fistulae are entities which can be avoided by appropriate early surgical care.

surrounding structures. Marked contamination of the deep tissue, involving directly the deep spaces, may occur. Foreign bodies may be driven into the area and near-by tissue damaged by the traumatic force. Anaerobic infection may be likely, especially when significant foreign bodies are not removed. Tetanus and gas-forming infection therefore should be feared.

Delayed or secondary effects within these deep wounds are edema of the larynx, varying degrees of tracheobronchitis, pneumonitis, infection along the prevertebral fascia with possible mediastinitis and secondary hemorrhage. If a suppurative process develops, not only mediastinitis, but also jugular septic phlebitis, must be feared. In all of these complications, glottic edema frequently may be the key to a chain of events leading to fatality. Maintenance of an adequate airway is essential and, therefore, early tracheotomy frequently will be necessary as a prophylactic lifesaving maneuver, either at the time of primary repair or later when dyspnea develops.

Vascular Injuries. Fortunately, injuries to the great vessels in the neck and upper thorax occur rather infrequently. The significant vessels involved are the carotids, thyrocervical axis, vertebral, subclavian and innominate arteries, the jugular, subclavian and innominate veins and the arch of the aorta. Hemorrhage from these vessels can be so rapid and severe as to exsanguinate the patient before definite care can be attempted. In addition, strangulation by compression of the trachea may result from the effects of a massive, rapidly expanding, subfascial hematoma. Fatal cerebral thrombosis or varying degrees of the hemiplegic state may be late central complications of carotid injury in those who survive thrombosis. Late local effects consist in the formation of carotid aneurysms and arteriovenous fistulae.

First aid for both arterial and venous hemorrhage should consist of direct packing of the wound reinforced by a gentle compressive dressing. While formidable bleeding may suggest the need for a more vigorous and more specific on-the-spot type of surgical "first aid," one should withstand the temptation to perform such heroic attempts because sutures and ligatures applied under adverse and contaminated circumstances add to infection and increase the possibility of intravascular thrombosis. Such a procedure merely complicates the later definitive surgical care. Immediate efforts should be directed toward proper transportation of the

injured patient to a hospital where deliberate surgical repair can be accomplished.

Visceral Injuries. Penetration of the hollow cervical viscera, that is, the oropharynx, esophagus, larynx and trachea, by the wounding mechanism permits bacterial invasion to take place along the fascial planes of the neck. Infection from these mucous membrane-lined structures, especially from the pharynx and esophagus, is far more significant than infection into the wound from without. In a bullet or knife wound, the presence of subcutaneous emphysema, noted either by physical examination or by soft-tissue roentgenogram, indicates that one or more of these organs have been perforated. Wounds involving the floor of the mouth, pharynx or esophagus can be expected to heal quite well if appropriately repaired with adequate drainage of the visceral space. Small nasogastric tubes should be used for feeding purposes. On the other hand, if infection develops, these wounds are characterized by a foul exudate with considerable leakage of saliva. Edema of the glottis, mediastinitis or abscess formation with severe, secondary, venous hemorrhage may result. Although there may be difficulty with nutrition and healing is slow, the resultant orocutaneous fistula in some patients eventually may close spontaneously, but in others secondary closure will be required.

When the larynx or trachea has been cut across or severed by a bullet, there is a tendency for the parts to separate. A temporary tracheotomy may be required to facilitate good oxygen exchange and to permit safe transportation. If the division is complete, the lower end may retract beneath the sternum and be drawn downward with each inspiratory effort, especially if the distal opening is covered with soft tissue. When early repair is not possible, the lower cut end can be brought to the surface and a tracheotomy tube inserted as a temporary measure. Reconstruction can be done at a later time.

Treatment. The general principles of wound treatment in the neck are the same as those for any other part of the body, except that the local anatomy produces a few problems peculiar to the neck. Control of bleeding and maintenance of an adequate airway are of prime importance. In serious injuries, blood transfusion may be required to stabilize cardiovascular mechanics before surgical intervention can be attempted. A temporary tracheotomy performed under local anesthesia should be considered at this

stage if respiratory obstruction is present. Atropine will help to diminish the bronchial secretions, but suction through the tracheotomy opening may be necessary to accomplish an adequate bronchial toilet.

After the general condition of the patient has improved, endoscopic and roentgen-ray examination can be carried out with more care, in order to determine more fully the extent of the injury and to detect the presence of any hidden foreign bodies. If multiple injuries are present, all must be properly assessed and therapeutic priority established. With this information at hand, the wounds then can be repaired.

A general anesthetic should be administered, either by an endotracheal tube or in conjunction with the tracheotomy. Selection of the anesthetic for the patient with a serious neck injury is very important because a high oxygen content is absolutely essential. Although local anesthesia may be used for many elective surgical procedures in the neck, it is not suitable for these patients.

Following appropriate skin cleansing, the packing is removed from the depths of the wound. This is replaced by more specific pressure and each vessel is carefully ligated as fresh bleeding recurs. In knife or bullet wounds, a generous extension of the wound ordinarily will be necessary to obtain satisfactory exposure and control of all bleeding points. Bleeding from large veins may be more troublesome to control than that from arteries, because vein walls are so fragile that they tear easily when handled. Ligation of a large vein requires good exposure and gentle technique. Débridement of devitalized tissue and removal of all foreign bodies are done as indicated. Clots are removed and the wound generously irrigated with saline solution.

While major veins in the neck can be interrupted without fear of central complications, every effort should be made to restore vascular continuity when the carotid artery has been injured. Ligation of the common carotid artery involves the risk of hemiplegia or fatality when it is performed under general anesthesia and in the presence of shock. Suture of lacerations of the carotid wall or end-to-end anastomosis should be performed whenever possible. When large defects are present, arterial homografts or flexible plastic substitutes have proved to be successful on a few occasions.

A complete anatomic survey then is necessary in order to identify lacerations in the viscera. Small defects in the trachea can be

sutured and covered with near-by thyroid or muscle. Sometimes, a two-layered closure of the pharynx can be obtained if the surrounding tissues are properly mobilized. Major defects in the larger muscles can be closed by loose suture. When viscera have been perforated, no attempt should be made to close the deep cervical fascia. A small, thin, rubber drain can be permitted to come to the outside from the visceral space, but it never should be left in direct contact with the sutured wall. These maneuvers serve to decompress the retropharyngeal and visceral spaces and therefore diminish the potential of mediastinal infection. Gentle suction drainage will facilitate both wound healing and postoperative nursing care.

In the course of immediate after-care all patients with deep neck wounds should receive penicillin or other appropriate antibiotics in order to reduce the likelihood of infection. Nutrition and fluid balance can be maintained by the early and continuous use of small nasogastric tubes. The late complications of persistent orocutaneous fistula, carotid aneurysm and various arteriovenous fistulae are entities which can be avoided by appropriate early surgical care.

Larynx and Trachea

By F. JOHNSON PUTNEY, M.D.

F. JOHNSON PUTNEY started and matured his professional career at Jefferson Medical College and its hospitals following his college education at Furman University in South Carolina. He based his present specialized interests upon a firm foundation of a two-year rotating internship and residency training in otolaryngology.

DISEASES OF THE LARYNX

The larynx may be examined by inspection by mirror or direct laryngoscopy, by palpation or by roentgenographic or planographic study of the neck.

Injuries. Contusions resulting from falls, blows or other injuries are common. When hematoma develops, absorption is the rule without incision and drainage. Subperichon-

Pain is almost invariably present and is made worse by swallowing. Tracheotomy may become necessary.

Fractures. The larynx is protected by the lower jaw and its mobility over the cervical spine allows it to roll with a blow so that the force necessary to cause fracture must be extreme and applied after the organ is fixed. The fracture may involve either the thyroid or cricoid cartilage, but rarely both, unless the force is a crushing one. Fracture of the cricoid cartilage is serious and disabling.

Healing occurs by fibrous union. Perichondritis may follow infection and increase the difficulty. Unilateral paralysis due to recurrent laryngeal nerve damage is a rare complication following cricoid fracture.

The symptoms are pain on swallowing, hoarseness and cyanosis. Soft tissue edema and redness, with or without an external wound, may make palpation of the fragments difficult, but abnormal mobility and crepitus are usually present. Subcutaneous emphysema establishes the diagnosis. Roentgen-ray examination generally discloses the fracture and is helpful in determining the position of the fragments.

It may be necessary to insert a nasal feeding tube to overcome the extreme odynophagia. Tracheotomy must be promptly performed unless the patient can be kept under close observation for subsequent obstructive dyspnea from hemorrhage and edema.

Wounds. Wounds of the larynx are commonly the result of war injury or suicidal attempts by cutting or shooting. If a large neck vessel is injured, death may result from hemorrhage or asphyxiation. Treatment consists in arresting the hemorrhage, controlling infection, performing a tracheotomy if there is dyspnea and closing the wound with drainage. Injury to the laryngeal cartilages, particularly the cricoid, is commonly followed by cicatricial stenosis.

Bilateral Paralysis of the Larynx (Bilateral Recurrent Paralysis, Bilateral Abductor Paralysis). When bilateral paralysis of the muscles of the larynx occurs, both vocal cords are in the midline position of adduction.

Paralysis of both posterior cricoarytenoid muscles is commonly observed in bulbar lesions but may be caused by involvement of the recurrent nerves in carcinoma of the cervical esophagus, carcinoma of the thyroid gland and trachea, malignant disease of the mediastinal lymph nodes and by trauma to the recurrent nerves during thyroidectomy.

In addition to the causative factors, the loss of function of the abductor muscles of the vocal cords interferes with the respiratory function of the larynx.

The voice may not be changed, but the patient will speak as though breathless. This is caused by inspiratory dyspnea due to failure of the vocal cords to separate during inspiration.

By mirror laryngoscopy, the vocal cords are found in adduction. On inspiration, there is no separation and only a slight drawing

downward and inward of the edges of the vocal cords. The cause of the paralysis must be determined and the paralysis differentiated from cricoarytenoid ankylosis.

The prognosis is unfavorable because sudden death from asphyxia is always imminent. If paralysis is complete, there is no hope of spontaneous improvement, if partial, as in syphilis or viral infections, appropriate treatment may be beneficial.

Treatment of complete paralysis consists of tracheotomy followed by surgical restoration of an adequate laryngeal airway. Removal of the cause rarely is possible. Anastomosis of nerves in patients with paralysis due to injury has not been successful. A one-way tracheal cannula can be employed. Ventriculocordectomy has been unsatisfactory. Submucous resection of a vocal cord has been superseded by either mobilization and lateral fixation of an arytenoid cartilage or arytenoidectomy and lateral fixation of the vocal cord. These procedures are highly successful.

Infection. Infection of the larynx becomes of surgical importance when the inflammatory changes and associated edema produce stenosis and necessitate tracheotomy. Pyogenic abscess may develop in the epiglottis, arytenoids or ventricular bands and must be differentiated from an underlying foreign body or malignant disease. The abscess may rupture and discharge pus or it may have to be incised and drained by direct laryngoscopy.

Acute Inflammatory Edema of the Larynx (Edema of Glottis, Obstructive Laryngeal Dyspnea). Stenosis of the larynx may result from acute laryngitis, acute infectious diseases, acute inflammatory processes involving surrounding structures, abscess of the larynx, acute septic laryngotracheobronchitis, injuries or wounds of the larynx or neck, burns or scalds of the larynx, inhalation of irritating vapors, chondritis and perichondritis, chronic diseases or foreign bodies.

The pathologic changes are those of the underlying cause together with inflammation and edema involving the submucous tissues above and below the vocal cords.

The symptoms produced are those of obstruction to the airway with disturbances of the voice and general systemic reactions. Obstruction to the laryngeal airway is characterized by inspiratory indrawing of the soft tissues of the thoracic cage at the suprasternal notch, epigastrium and intercostal, supraclavicular and infraclavicular spaces. Restlessness, ashy gray pallor and increas-

ing pulse and respiratory rates are observed. Cyanosis occurs late and is a danger signal.

The signs of obstructive laryngeal dyspnea are diagnostic. Inspection of the larynx, palpation of the neck, roentgen-ray examinations, general systemic studies and the history are usually required in order to arrive at an etiologic diagnosis.

The prognosis depends on the cause. The dyspnea can be relieved by tracheotomy.

In simple cases, inhalation of detergent and medicated vapors, the use of properly humidified oxygen and general medical measures may suffice. Sedatives must be avoided. If dyspnea is marked, tracheotomy becomes necessary. This should not be delayed until an etiologic diagnosis is made but must be promptly executed.

Noninflammatory edema of the larynx, as observed in patients with nephritis, angioneurotic edema or passive congestion due to venous obstruction, becomes of surgical importance only when tracheotomy is required to relieve the obstruction.

Chronic Stenosis of the Larynx (Cicatricial Stenosis of the Larynx). The laryngeal airway may become narrowed by cicatricial changes. The most common cause is improperly performed tracheotomy or faulty aftercare. Other causes may be syphilis, tuberculosis, injuries, chondritis, perichondritis, foreign body and abscess.

The normal structures are replaced by cicatricial tissue with narrowing of the airway, fixation of the vocal cords and often loss of a part of the normal supporting cartilaginous framework of the larynx. If tracheotomy has been improperly performed, a portion of the cricoid or thyroid cartilage may be lacking.

The chief symptom is an inability to secure any or sufficient air through the normal airway. Voice disturbances vary from hoarseness to aphonia. There is an inability to decannulate after tracheotomy.

Examination of the larynx reveals a narrowing or obliteration of the airway, the extent and degree being determined by direct laryngoscopy, palpation of the neck, roentgen-ray and planographic examination. Retrograde laryngoscopy and tracheoscopy may be necessary.

The prognosis is good if there is little or no loss of cartilage, but months or years of treatment may be necessary to secure a good result.

In moderate degrees of stenosis, laryngoscopic dilation may be adequate. Anterior web stenosis is readily repaired by insertion of a metal (tantalum) or plastic stent. In

marked cases, surgery must be resorted to and consists of laryngostomy, removal of sufficient cicatricial tissue to re-establish the airway and the use of some form of mold to maintain the airway during the process of healing with or without the aid of a skin graft. In the open method, a trough corresponding to the stenosed airway is maintained by the use of a dilating apparatus. When a satisfactory airway has been secured, the fistula is closed by plastic operation. In the closed method, after the airway is re-established a rubber or plastic tube is transfixed in the larynx with a silver wire and the neck closed. The indwelling stent is removed perorally after a number of weeks or months when epithelization is complete.

Benign Tumors of the Larynx. The common benign tumors of the larynx are papillomas and inflammatory lesions which are not true neoplasms. These inflammatory tumors consist of polyps, postintubational granulomas, localized edematous membrane and areas of thickened epithelial change. The true tumors consist of fibromas, angiomias, lipomas, cysts and papillomas. Two types of papillomas are recognized: those occurring in adults which are either single or multiple, villous-like, pedunculated or flat, and those occurring in children which tend to recur after surgical treatment, are usually numerous and resemble warts.

The principal occurrence of benign tumors is in adults, more often in males than in females. These neoplasms are commonly produced by vocal abuse or submucosal hemorrhage in the presence of acute infection.

The lesions vary in color from pale to dark red, in contour from smooth to irregular, and in shape from pedunculated to sessile. They are commonly found on the vocal cords but occasionally involve the ventricular bands. They generally are single but occasionally are multiple. Cysts of the aryepiglottic fold and vallecula are frequently observed in routine laryngeal examinations, but they very seldom produce symptoms.

Benign tumors of the larynx neither disappear spontaneously nor recur after surgical treatment. The chief danger consists in dyspnea when they enlarge sufficiently to obstruct the airway.

Early, rapidly increasing huskiness along with an unstable voice and easy voice fatigue are common symptoms. No symptoms are produced from the lesions involving the epiglottis, aryepiglottic folds and arytenoids unless the tumor is large, when a fullness in

the throat or difficulty in swallowing develops.

Mirror laryngoscopy generally uncovers the lesion. It must be differentiated from carcinoma by histologic study.

Removal is accomplished by direct laryngoscopy or suspension laryngoscopy with suitable forceps.

Malignant Tumors of the Larynx. The majority of the malignant tumors of the larynx are squamous cell carcinomas but sarcoma, rhabdomyosarcoma, plasmacytoma and chondroma also occur. Almost all of the malignant lesions develop in the mucous membrane, but a few arise in the deeper soft tissues or in the cartilages of the larynx.

Carcinoma. In a consecutive series of 1493 cases at Jefferson Hospital the average age of the patients was 58.9 years, but the disease was occasionally encountered in individuals of both extreme age periods, the youngest patient being 18 years of age and the oldest 88. In this group the males predominated in a ratio of 13:1. A family history of cancer was obtained in 19 per cent of the patients.

In this series, 88 per cent of the patients smoked and excessive smoking was present in 52 per cent. In a certain definite percentage of the subjects, keratosis preceded the development of carcinoma. Squamous cell carcinoma predominated with an occasional papillary carcinoma.

Carcinoma most often affects the anterior half of the larynx and usually originates on the vocal cords so that hoarseness occurs early and becomes persistent and progressively worse. The lesion should be suspected in any patient with hoarseness of longer than three weeks' duration. In lesions involving the epiglottis and posterior portion of the larynx, the voice may be normal, but the patient complains of vague discomfort in the throat, a sensation of fullness or lump in the throat. In laryngeal carcinoma, aphonia and pain are late symptoms. When located on the vocal cord, even the smallest lesion produces hoarseness. Occasionally, the appearance of enlarged cervical lymph nodes first directs attention to the upper respiratory tract and a malignant lesion of the larynx may be uncovered. In extensive lesions, dyspnea becomes marked and tracheotomy may be necessary before definitive treatment to the larynx can be undertaken.

Mirror examination reveals an uneven vocal cord with a rough nodular surface or an infiltrating lesion with fixation of the involved vocal cord. Ulcerating and proliferat-

ing lesions of the epiglottis, arytenoids, aryepiglottic folds and posterior portion of the larynx may be observed. Vocal cord cancer may extend above the surface or beneath the mucosa, spread to the opposite cord and ultimately extend outside the larynx, eroding the cartilages and obstructing both the air and food passageways. Metastasis to the cervical lymph nodes is often the first indication of spread outside of the larynx. Direct laryngoscopy, with removal of all or a portion of the lesion, is necessary for histologic confirmation of the clinical diagnosis.

A high portion of cures is obtained in laryngeal carcinoma as compared with malignant lesions elsewhere in the body, chiefly because of the anatomic construction of the larynx (enclosure in a cartilaginous box) and poor lymphatic drainage, both of which contribute to relatively late metastasis. Surgery yields a greater number of five-year cures than do other methods of treatment. In early malignant lesions of small extent and limited to a freely movable vocal cord, removal of the growth by laryngofissure is the prevailing operative procedure. Early diagnosis enables these lesions to be discovered while the growth can still be adequately removed and the voice box retained. In early cases, endolaryngeal removal by cauterization through suspension laryngoscopy or irradiation therapy is also successful in a large number of cases. In more advanced disease, total laryngectomy is needed and when palpable lymph nodes are present in the cervical area block dissection of the neck should always be included in one stage. In carcinoma of certain areas, such as the epiglottis, subglottic region, arytenoids and aryepiglottic folds, without enlarged cervical nodes, laryngectomy combined with radical neck dissection offers the best chance of survival. When total laryngectomy is employed, the resulting loss of the laryngeal voice need not be disabling for most of these patients develop satisfactory buccal voices.

DISEASES OF THE TRACHEA

Injuries. The trachea is injured commonly following falls, blows or wounds of the neck. The tracheal rings may be torn or fractured, or the interannular membrane may be lacerated. Dyspnea is present, depending on the degree of narrowing of the airway. If vessels have been injured, there is hemorrhage. Subcutaneous emphysema with extension into the mediastinum may result

from laceration of the trachea. Pain on swallowing may be severe. The history with the local evidences of injury is usually diagnostic. Tracheoscopy may be necessary. The prognosis depends on the extent of the injury and the involvement of the surrounding structures, notably blood vessels and esophagus.

Hemorrhage should be controlled first. Tracheotomy is indicated for dyspnea and to decompress a sucking wound. Incised wounds should be repaired with drainage. Cicatricial stenosis is treated by dilation or by plastic repair through a tracheostomy performed as in laryngostomy.

Infection. Simple catarrhal infections of the trachea present no surgical problems. Chronic infections such as tuberculosis and syphilis are of surgical importance if stenosis results.

Fractures. Crushing injuries or penetrating wounds may produce collapse of the trachea, a longitudinal tear or rupture from the bronchus at the bifurcation. Pain beneath the sternum is a common accompaniment of fracture and dyspnea may become marked. Subcutaneous and mediastinal emphysema develops rapidly. Tracheotomy is necessary if a tension pneumothorax occurs or the emphysema progresses.

Tracheoesophageal Fistula. Congenital fistulae produce symptoms soon after birth when the infant begins to take liquids. Prompt recognition of the significance of symptoms followed by iodized oil instillation into the esophagus is necessary so that surgical repair can be accomplished to prevent aspiration and pneumonia. In adults, tracheoesophageal fistula is usually a complication of carcinoma of the esophagus and the prognosis is poor.

Tumors of the Trachea. Benign tumors of the trachea are rare but may occur in any portion of the trachea, generally in the upper third or near the bifurcation. Papillomas, fibromas, lipomas, lymphomas, chondromas and osteomas have been reported. Adenoma not infrequently develops in the trachea and gives rise to obstructive dyspnea and a marked wheezing. When small or pedunculated, benign tumors can be removed bronchoscopically. Otherwise, surgical exploration with removal of the tumor and repair of the tracheal defect is necessary.

Squamous cell carcinoma is the most common malignant tumor of the trachea. Obstruction to the airway with hemoptysis and the presence of a wheeze is frequently encountered. Marked dyspnea and pneumoni-

tis develop later. Endoscopic visualization and biopsy establish the diagnosis. Unless the carcinoma is an extension downward from the larynx, the treatment is unsatisfactory. Radiotherapy has been disappointing. The best treatment is surgical excision with immediate repair of the trachea by a plastic operation utilizing a prosthetic tube until epithelization becomes complete.

TRACHEOTOMY

While tracheotomy is essential in the treatment of obstructive laryngeal lesions producing dyspnea, it is also employed to relieve secretional anoxia of the lower respiratory tract. The patient may not be able to remove accumulated secretions and aspiration through the tracheotomy tube may be lifesaving. It has become increasingly useful in sustained postoperative atelectasis, poliomyelitis, tetanus, botulism, eclampsia, neurologic depression from head injuries, comatose states and following intrathoracic surgical procedures and operations on debilitated patients.

The chief cause of complications is improper surgical technique either from placing the tube too high, causing pressure necrosis of the cricoid cartilage, or tight closure of the wound so that infection with subsequent tracheal stenosis prevents decannulation. Mediastinal emphysema is frequent but not serious unless tension pneumothorax develops, when prompt decompression of the pleural cavity is necessary. When there is injury to the cricoid cartilage, laryngeal stenosis may follow. If the tracheotomy tube is changed prior to forty-eight hours and stabilization of the tract has not occurred, the cannula may be passed alongside the trachea into the mediastinum and introduce infection. After the second day, the tube should be changed daily and a clean tube inserted.

The opening into the trachea is made in the midline below the first tracheal ring, preferably below the second ring. General anesthesia is contraindicated and the operation is performed under a local anesthetic or no anesthesia is employed. Tracheotomy should be performed early so that it can be carried out in an orderly manner and before there is imminent danger of asphyxiation. Delay may lead to an emergency procedure which commonly results in a poorly performed operation. The skin incision extends from the thyroid notch to the suprasternal notch (Fig 8). Division and ligature of the thyroid isthmus are generally needed to

Fig. 8.

Figure 8. Vertical incision in the midline of the neck from the thyroid notch to the suprasternal notch is made for wide exposure of the trachea.

Fig. 9.

Figure 9. Segment of the second or third cartilaginous ring is removed from the trachea before insertion of tracheotomy tube.

expose the tracheal rings. A segment of the second or third tracheal ring should be removed except in young infants when the second or third ring is incised in the midline and the opening dilated to allow introduction of the tracheotomy tube. (Fig. 9). The tracheotomy cannula should be of proper size and shape for the individual. The wound should not be sutured but left open.

The after-care consists of keeping the airway open by wiping away coughed-up secretions, cleaning the inner cannula and aspirating secretions from the trachea through the cannula. With crusting of the secretions, bronchoscopy through the tracheotomy fistula may become necessary in order to keep the airway open.

FOREIGN BODIES IN THE AIR PASSAGES

The lodgment of a foreign body in the larynx or trachea is not as common an accident as lodgment in the lower air passages. The most common cause of aspiration of a foreign body is carelessness in holding objects other than food in the mouth. These are generally drawn into the respiratory passages with a deep inspiration when the patient is laughing, coughing, sneezing, singing or talking. The pathologic changes depend on the character and location of the object, the length of sojourn and whether or not there is obstruction. Recent nonobstructive foreign bodies may produce no changes other than slight inflammation at the point of lodgment. Obstructing foreign bodies will ultimately cause suppuration. The initial or immediate symptoms are chok-

ing, gagging and coughing. The subsequent symptoms depend on the size, shape and character of the foreign body and the point of lodgment. Peroral endoscopic removal is the only means of treatment worthy of consideration.

The common symptoms of a foreign body in the larynx are dyspnea and disturbances in the voice. There may be a cough and wheezing. Large, obstructive foreign bodies may produce asphyxiation.

Migratory foreign bodies in the trachea produce paroxysmal coughing. An audible slap and palpatory thud may be elicited. Dyspnea and wheezing respiration may be present. If the foreign body causes obstruction, there is commonly bilateral obstructive emphysema. Bronchoscopic removal is indicated.

PERORAL ENDOSCOPY

Direct visualization of the interior of the trachea and larger bronchi is possible by the use of specially illuminated rigid hollow tubes. These are introduced through the mouth and serve as specula to draw aside the structures that hinder the view and bring inaccessible areas into view. The direct laryngoscope is a laryngeal speculum, the bronchoscope is a tracheal or bronchial speculum.

A special instrumentarium is necessary. Certain instruments are regularly used in the common procedures while other instruments are required only in special cases. The normal air passages cannot be dilated beyond their normal caliber. It is therefore neces-

sary to have special-sized instruments for infants, children and adults.

Acquired skill in the use of endoscopic instruments may be secured only by educating the eyes and fingers. As this cannot be secured on the living patient, the fundamental principles are best taught on the cadaver. When skill and proficiency have been attained, experience should be secured on narcotized dogs so that the normal physiologic movements may be observed and studied.

General anesthesia is not necessary and is often undesirable, but preliminary sedation is employed immediately preceding operation the larynx and trachea of the adult patient are anesthetized, preferably with a 0.5 per cent solution of Pontocaine or a 4 per cent solution of cocaine, by fractional instillation. In children the use of local anesthesia is unsafe.

The patient should be in the dorsal recumbent position with the head and shoulders extending beyond the end of the table. The head is supported by the left hand of

the assistant who is seated at the patient's right. With his right hand the assistant holds the mouth gag in the left angle of the patient's mouth. The shoulders are held flat on the table by a second assistant. For laryngoscopy, the operator exposes the larynx with the direct laryngoscope held in the left hand, leaving the right hand free for manipulation and introduction of instruments, or the laryngoscope is suspended or fixed in position by mechanical means. To examine the trachea or bronchi, the bronchoscope is introduced directly through the larynx into the trachea. The skilled technique of the various procedures involved requires study and training.

THE THYROID AND PARATHYROID GLANDS

By GEORGE CRILE, JR., M.D.,
and ROBERT W. SCHNEIDER, M.D.

GEORGE CRILE, JR., a Clevelander and son of a distinguished surgeon, was educated at Yale University and the medical school of Harvard University. He has a continuing interest in thyroid disease which was extensively studied in pioneer clinical research at the Cleveland Clinic. He has a wide range of interests in natural history.

ROBERT WOODROW SCHNEIDER was born and raised in Wisconsin and received his education at the University of Wisconsin. He received his training in internal medicine at the Cleveland Clinic, became a staff member in the Department of Endocrinology and now is in practice in Salem, Oregon.

THE RELATIONSHIP BETWEEN THE STRUCTURE AND THE FUNCTION OF THE THYROID GLAND

Many of the changes in the structure of the thyroid gland are compensatory in nature. A compensatory mechanism in which the pituitary increases its output of thyroid-stimulating hormone (TSH). This increase in TSH causes hypertrophy, hyperplasia and hyperfunction of the thyroid. If stimulation is continued over long periods, many complicated changes in the structure of the thyroid may result.

For many years, in accordance with the studies of Marine, it was believed that a deficiency of iodine was the primary factor in the production of endemic goiter. Iodine is an essential part of the thyroid hormone. Without some trace of iodine it would be

impossible for the thyroid to manufacture any hormone at all. But it appears that the role of iodine deficiency is not so important in the production of goiter as was once believed. Particularly in these days when much of our salt is iodized and when foods are shipped from the coasts to the interior, the intake of iodine is probably adequate to supply the needs of the thyroid. Other factors besides deficiency of iodine appear to play a major part in the production of goiter. Among these are the goitrogens.

Substances like thiourea, thiouracil, vegetables of the rutabaga family, soybeans, cabbage, thiocyanate, sulfonamides, and other compounds which block the enzymatic system of the thyroid, depress the output of thyroid hormone. Secondly, through stimulation of the pituitary, this block results in hypertrophy and hyperplasia of the thyroid gland. The administration of iodine often

diminishes the hyperplasia, just as it inhibits the compensatory hyperplasia that follows removal of a large part of the thyroid gland, but it does not altogether prevent it. In short, there are factors other than deficiency of iodine which cause hypertrophy and hyperplasia of the thyroid and iodine does not necessarily give full protection against goiter induced by feeding these substances.

Heredity, as well as exogenous factors, plays a part in the development of goiter. There may be a strong familial tendency toward goiter, and mother and daughters often are affected. Although the cause of this hereditary tendency has not been determined, it is possible that it lies in some intrinsic failure of the enzymatic system of the thyroid to produce an adequate amount of thyroid hormone. This failure results in an attempt at compensation, in the stimulation of the thyroid by the pituitary and in a prolonged state of thyroid strain. It is from this thyroid strain that many of the diseases of the thyroid may arise.

ENDEMIC GOITER

Prolonged stimulation of the thyroid gland by thyrotropic hormone results at first in hypertrophy and hyperplasia. Finally, with long-continued stimulation, areas of degenerating or regenerating epithelium form nodules in the thyroid. The incidence of nodules in the thyroid is extremely low in babies and children but, gradually throughout life, it rises until in areas of endemic goiter practically everyone in the older age groups has a nodular goiter. This is one of the end results of prolonged thyroid strain.

In contrast to the multinodular endemic goiters which are the end result of a physiologic process of attempted compensation, there are true tumors of the thyroid, solitary tumors just like adenomas and carcinomas that occur elsewhere. These do not often appear to be a part of the process of multinodular change. They may be either benign or malignant. Usually they are single. These tumors are significant because they represent true neoplasia. They are much more apt to be malignant than are the involutionary nodules in a multinodular goiter.

TYPES OF HYPERTHYROIDISM

There are two types of hyperthyroidism: Graves' disease and nodular goiter with hyperthyroidism. Each of these has a different cause. In Graves' disease, there appears to be stimulation of the pituitary as well as

of the thyroid. The exophthalmos of hyperthyroidism is probably the result of an increased output of pituitary hormone rather than the result of the hyperthyroidism itself. Many believe that the hyperthyroidism of Graves' disease is the result of stimulation by an excess of TSH, but this relationship has not been proved.

In nodular goiter with hyperthyroidism, the hyperthyroidism appears to be the result of the autonomous hyperfunctioning of thyroid nodules which developed as a part of an endemic goiter. Eye signs do not occur in patients with nodular goiters unless the nodules are an incidental finding in the hyperplastic gland of Graves' disease.

The symptoms of hyperthyroidism are similar in both Graves' disease and in nodular goiter with hyperthyroidism. But in Graves' disease, occurring as it does about a decade earlier than nodular goiter with hyperthyroidism, there appears to be a greater restlessness, a greater brightness of the eyes, more sweating, more warmth of the skin and more tremor. In short, the signs of stimulation of the sympathetic nervous system are more obvious in Graves' disease than in nodular goiter with hyperthyroidism. In nodular goiter with hyperthyroidism, cardiac symptoms are apt to predominate, probably because of the older age and the increased incidence of intrinsic heart disease in the patients affected.

DIAGNOSIS OF HYPERTHYROIDISM

Most of the symptoms and signs of hyperthyroidism can be explained on the basis of increased oxidation. The increased pulse rate and the increased pulse pressure are necessary because of the increased demand for oxygen and for blood to bear it. The loss of weight, in spite of a good appetite, is evidence of the hypermetabolism. Increased body temperature, warmth of the hands and sweating are a part of the same overactivity.

The diagnosis of hyperthyroidism should not be made on the basis of symptoms alone. Hyperthyroidism is an organic disease. It gives objective evidence of its presence. Nervousness is much more apt to be the result of causes other than hyperthyroidism. Choking sensations and globus hystericus are rarely associated with thyroid disease.

Most of the mistakes in the diagnosis of hyperthyroidism are made because dependence is placed on the patient's symptoms, instead of upon the objective signs of increased metabolism. If a reliable laboratory

is available, the basal metabolic rate is an extraordinarily accurate index of hyperthyroidism. It is of little or no value unless done by a well-trained technician under basal conditions. The determination of protein-bound iodine is valuable in those patients who have not had iodine. When done accurately, it is of about the same order of reliability as the basal metabolic rate. Just as the basal metabolic rate may be elevated in conditions other than hyperthyroidism, such as essential hypertension, cardiac decompensation and leukemia, so may the protein-bound iodine be elevated in certain of the hypofunctional hyperplasias of the thyroid, as well as when the patient has been taking iodine in large doses.

If the patient has not been taking iodine, study of the uptake of radioactive iodine by the thyroid is a valuable diagnostic test. But this test, too, has its limitations. It may be elevated in nonfunctional hyperplasias when no hyperthyroidism is present.

There is no laboratory test which is 100 per cent accurate in the diagnosis of hyperthyroidism. Reliance should not be placed on the laboratory alone nor should a diagnosis of hyperthyroidism be made unless there is objective evidence of this disease.

TREATMENT OF HYPERTHYROIDISM

There are three kinds of effective treatment for hyperthyroidism: the antithyroid drugs, thyroidectomy and radioactive iodine.

The antithyroid drugs are of limited value in the definitive treatment of hyperthyroidism. The recurrence rate after withdrawal of treatment is high, amounting to about 50 per cent in patients with Graves' disease, and to a much higher figure in those with nodular goiter with hyperthyroidism. Since treatment with antithyroid drugs must be prolonged, requires medical supervision and is costly, these drugs are gradually falling into disuse. At the present time they are being used more to prepare patients for surgery, or as therapeutic trials, than as definitive means of treatment.

Thyroidectomy is an effective way of controlling hyperthyroidism. In nodular goiter with hyperthyroidism, thyroidectomy is nearly ideal. Following operations for nodular goiter with hyperthyroidism, the recurrence rate of hyperthyroidism is less than 1 per cent and, unless total thyroidectomy is performed, the incidence of postoperative hypothyroidism is practically nil. In the hands of competent surgeons, the morbidity and mortality of operation are low. Unless

some better way of treating this disease develops, thyroidectomy will continue to be employed as the preferred treatment for the majority of patients with nodular goiter with hyperthyroidism.

In Graves' disease, the situation is quite different. After thyroidectomy, the rate of recurrence is high, amounting to as much as 15 per cent at the end of five years if conservative subtotal thyroidectomies are done, and to 3 or 4 per cent even when almost all of the gland is removed. On the opposite side of the ledger, hypothyroidism, or myxedema, occurs in as high as 15 or 20 per cent of the subjects if a very radical thyroidectomy is done. Only if a great deal of the thyroid tissue is left, thereby running a high probability of recurrence, can the incidence of myxedema be kept as low as 3 or 4 per cent. Since there is no way of predicting which patient is going to develop hypothyroidism after operation, which is going to remain euthyroid and which will develop a recurrence of hyperthyroidism, it is obvious that thyroidectomy is not an ideal treatment for Graves' disease.

Radioactive iodine is a quick, safe, economical and simple method of treating the hyperthyroidism of Graves' disease. It is less effective in nodular goiter with hyperthyroidism because larger doses are required and because the nodular goiter does not disappear as does the diffuse goiter of Graves' disease. Usually the nodular goiter gets smaller, but almost always it persists. From the standpoint of time, economy and sureness of action, radioactive iodine is less effective than surgery in the treatment of nodular goiter with hyperthyroidism.

In recent years, the trend has been toward using radioactive iodine in the treatment of patients with Graves' disease. At first, treatment was reserved for those patients in the oldest age groups or for those with recurrent hyperthyroidism. But as experience with this method of treatment increased, the age limits were gradually lowered and now some physicians are treating even children by this means. If children are to be treated, however, it is imperative that they should not be allowed to become hypothyroid after treatment. There is evidence that, in prepubertal children, radiation tends to induce cancer of the thyroid, and that the feeding of thyroid tends to prevent the development of cancer in irradiated glands. The amount of radiation that the thyroid receives is high and that which the rest of the body receives minimal; in fact, it is comparable to that received in

the course of an ordinary gastrointestinal series of x-ray studies. The thyroid's ability to concentrate iodine makes it possible for the thyroid itself to receive almost all the radiation while it spares the rest of the body. The fact that the radiation is mainly in the form of beta rays, which do not penetrate the tissue more than 1 or 2 mm., means that the surrounding tissues are not disturbed by the radiation. Finally, since the half-life of radioactive iodine is only eight days, there is no danger of prolonged radiation causing late changes.

So far, no more than the normally anticipated incidence of malignant disease has been reported following the use of radioactive iodine. If at some future date malignant lesions should begin to develop in those patients who were treated ten years or more ago, it would still be possible to compensate for this danger by removing the thyroids of those patients who more recently have been treated with radioactive iodine. Unless in the future some unforeseen contraindication develops, radioactive iodine will replace thyroidectomy in the treatment of all patients with Graves' disease. Thyroidectomy probably will remain the treatment of choice in those patients with nodular goiters and hyperthyroidism whose physical conditions are compatible with a low risk of operation.

THYROIDITIS

There are three types of thyroiditis: struma lymphomatosa (Hashimoto's thyroiditis), granulomatous (subacute) thyroiditis, and Riedel's struma.

With the diminishing incidence of nodular goiter, Riedel's struma has become so rare that it has almost disappeared. For all practical purposes, it can be disregarded. It is a nonspecific invasive fibrosis of not only the thyroid but also of all the tissues of the neck. It is quite impossible to remove a Riedel's struma. Usually, all that can be done is to cut into it and shell out the adenoma which commonly is encapsulated in the center of the fibrous mass. This often gives sufficient decompression to allow the patient to go on in comfort and for some unknown reason the fibrosis does not progress and, in fact, may appear to resolve somewhat after the nodule is removed.

Struma lymphomatosa is characterized by infiltration of the thyroid with lymphocytes and formation of germinal centers. The epithelium is often oxyphilic and functions poorly; varying degrees of fibrosis are present.

It appears that one of the primary defects in Hashimoto's thyroiditis is the failure in function of the thyroid epithelium. Recently Domach and Rott have shown that this failure may be the result of an autoimmune process directed against thyroglobulin, the thyroid cell itself or against both thyroglobulin and the cell. Failure of thyroid function probably stimulates the pituitary. Perhaps, as a result of prolonged thyroid strain, further decompensation occurs and may lead to either myxedema or to a compensatory hypertrophy of the thyroid gland. Thus, the clinical spectrum of struma lymphomatosa varies all the way from spontaneous myxedema in the adult, with a small fibrous gland which cannot even be felt, right up to the rapidly enlarging, large, nodular-feeling goiter which is so frequently considered to be composed of multiple adenomas and is often removed by surgeons. There is also a milder phase of this same disease, in which there are no oxyphilic changes in the epithelium, but lymphocytosis is present.

All of these lymphocytic types of thyroiditis respond specifically to the administration of desiccated thyroid. They do not require surgical removal. The diagnosis can be established by needle biopsy if necessary, but it is usually obvious as the result of the enlargement and firmness of the entire thyroid gland, the tendency toward hypometabolism and the fact that in these patients the administration of thyroid-stimulating hormone fails to cause any increase in the uptake of radioactive iodine.

Subacute thyroiditis, the third distinct type, bears no relationship to the other two. It appears to be infectious in origin. Perhaps it is the result of a virus infection which destroys part of the thyroid epithelium and allows colloid to escape into the tissues where it is treated as a foreign body and causes a foreign-body reaction. Histologically, it is characterized by fibrosis and by a foreign-body type of reaction with many giant cells present. It is a self-limited disease, which eventually ends in resolution without impairment of thyroid function.

The clinical spectrum in subacute thyroiditis varies from an acute disease associated with a high temperature, severe pain on swallowing, pain radiating to the ears and exquisite tenderness in the thyroid to a very low-grade chronic process in which there is a very hard tumor which may not be tender at all. Again, the diagnosis of thyroiditis is made by being able to outline the entire lobe of the thyroid, by the fact

that the lobe retains its normal shape and because the consistency is always hard. Sometimes the thyroiditis will start in one lobe and gradually migrate to the other. Usually both lobes are involved simultaneously.

Subacute thyroiditis responds specifically to the administration of cortisone in doses of 25 mg., given four times a day. The pain is relieved at once and in a few days the thyroid itself has lost its hard consistency, is normal in size and is no longer tender. Relapses are common after withdrawal of therapy. X-ray therapy, in doses of about 800 r, is also of value and appears to be more permanent in its effect than is cortisone.

Except for the almost nonexistent Riedel's struma, there are no indications for operating on thyroid glands which are the seat of thyroiditis. If the surgeon asks himself each time he examines a goiter, "Could this be thyroiditis?" the diagnosis can be made in the majority of cases with no difficulty.

NODULAR GOITER WITHOUT HYPERTHYROIDISM

Although goiters are not as large as they once were, nodular goiter is still a fairly common disease. In approximately 10 per cent of all adult women, small nodules can be felt in the thyroid gland. Nodules of 2 cm. or more in diameter can be felt in nearly 5 per cent of all older women. Since nodules in the thyroid are so common, removal of all nodular goiters would be impracticable and would certainly cause much more damage in the form of complications and operative deaths than would occur if most of the nodules were left alone.

A nodular goiter should be removed if the goiter is large enough to be of cosmetic importance; if the goiter is toxic; if there are symptoms of pressure; in a young individual if the goiter is extending into the thorax, and threatens, if it continues to enlarge, to cause trouble at a later date, and if the goiter is suspected of being malignant.

Many surgeons argue that all nodules in the thyroid are possibly cancer and that it is quite impossible to tell a cancer of the thyroid from a benign goiter. It is true that in many cases a definite diagnosis cannot be made, yet an experienced examiner can recognize between 80 and 90 per cent of all cancers of the thyroid. In many subjects, the involved lymph nodes are palpable. In many others, the consistency of the tumor, its occurrence in a young individual or its rapid

enlargement in an older individual arouses suspicion. Operation on thyroid nodules should not be conducted indiscriminately on all nodules in persons of all age groups but should be reserved for those patients in whom there are definite indications.

There is no evidence that adenomas of the thyroid commonly become malignant; in fact, all evidence is to the contrary. Most carcinomas of the thyroid are cancers from the beginning and never did originate in a benign tumor. It is true that nodules are present in the majority of thyroid glands in which cancer is present, but it is also true that nodules are present in the majority of thyroid glands of patients of the age of those who develop cancer. There is no clear-cut pathologic evidence that cancer often originates in benign adenomas.

CLASSIFICATION OF CANCER OF THE THYROID

Cancer of the thyroid can be classified in two broad categories, the papillary and the nonpapillary carcinomas (Table 1).

Papillary carcinoma is a special variety of cancer. It occurs most often in patients under the age of forty years. It may not be a true cancer at all. Often it fails to grow or to cause any difficulty over periods as long as twenty or thirty years. Sometimes, even when it has metastasized, the metastatic tumor will regress if the patient is given 3 grains or more of desiccated thyroid daily. This form of treatment is probably effective through suppression of the thyrotropic hormone of the pituitary.

Microscopic cancers of the thyroid, most of them of the papillary variety, can be found in 3 per cent of all thyroids removed at autopsy when serial sections are made. In 0.5 per cent, gross tumors are present.

Table 1. Classification and Incidence of Types of Malignant Tumors of the Thyroid (182 Cases)

	PER CENT
I. Papillary carcinoma	58.8
II. Nonpapillary carcinoma	
1. Encapsulated angioinvasive carcinoma	4.4*
2. Medullary carcinoma	3.9
3. Adenocarcinoma	8.3
4. Undifferentiated carcinoma	15.4
III. Sarcoma	
1. Lymphosarcoma	0.5
2. Reticulum cell sarcoma	3.3
3. Fibrosarcoma	1.1
IV. Secondary neoplasm and rare types	4.3
	100.0

* In recent years the incidence of encapsulated angioinvasive cancer appears to be increasing.

Fortunately, most of these tumors never grow or cause any trouble.

Many clinically recognized papillary cancers of the thyroid grow so slowly that they would not be fatal even if no treatment were given. But if papillary cancers of the thyroid are cut into and disseminated, they may implant themselves in the wound, recur locally in an invasive and unremovable manner or they may gain access to the blood stream and metastasize to lungs or bone.

Nonpapillary carcinomas of the thyroid are like other carcinomas elsewhere in the body. They occur mainly in individuals beyond the age of forty years. They vary in their degree of malignancy from the encapsulated angioinvasive carcinoma, which, except for its tendency to invade blood vessels, is indistinguishable from a benign adenoma, right up to the undifferentiated cancer which is one of the most devastating types of cancer there is. Between these two extremes lie two tumors of intermediate malignancy, both of them rare. The medullary carcinoma metastasizes to the regional lymph nodes, much like papillary carcinoma, but also may metastasize by the blood stream. The adenocarcinoma, also of intermediate malignancy, metastasizes primarily by the blood stream. All of the nonpapillary carcinomas of the thyroid have a tendency to metastasize early by the blood stream and the prognosis in all of them is therefore poor. The prognosis is best in the angioinvasive carcinoma because this is the slowest growing of the non-papillary malignant tumors.

TREATMENT OF CANCER OF THE THYROID

Sarcomas, highly malignant adenocarcinomas and undifferentiated carcinomas of the thyroid usually can be recognized without difficulty. In four-fifths of them, there is no history of a pre-existing goiter. The growth is rapid, the patient usually sees the surgeon within two or three months of the onset and symptoms of pressure, pain, hoarseness from invasion of a recurrent nerve or signs of distant metastasis often are present. Rarely is there any question of diagnosis. Treatment almost never succeeds in arresting the disease.

Attempts to remove these cancers usually result in rapid dissemination of the tumor through the blood stream and in prompt recurrence in the wound. In the patients in whom it is suspected that the cancer is highly malignant, it is better to confirm the diagnosis by needle biopsy and treat the

cancer by x-ray. Occasionally a satisfactory regression will occur. Almost never will a cure be effected.

Undifferentiated cancers do not take up enough radioactive iodine to make treatment effective. As a rule, there is no use trying treatment with radioactive iodine unless the cancer is sufficiently well differentiated to make colloid.

Adenocarcinomas of moderate malignancy and encapsulated angioinvasive carcinomas do not tend to metastasize to the regional lymph nodes, except in those advanced cases in which the capsule of the thyroid has been penetrated by the tumor. In these tumors, metastasis to regional nodes is almost always an indication of incurability for, when nodes are involved, distant metastasis usually has taken place. For this reason, the treatment of adenocarcinomas and encapsulated angioinvasive carcinomas is by total removal of the affected lobe and of the isthmus. Neck dissection adds nothing to the curability of these cancers. The main thing is to remove them completely and not to break their capsules. If the tumor is cut into, or if the capsule is ruptured, tumor tissue may be seeded in the incision. Although many patients with this kind of cancer may live for many years with local recurrences or distant metastases to lung or bone, about 70 per cent of them eventually die of their disease. Only occasionally is x-ray therapy effective, but in those tumors which make colloid, radioactive iodine gives promise of control.

Since medullary carcinomas metastasize both to the lymph nodes and through the blood stream, even the most radical of neck dissections is rarely curative. Patients may survive five to ten years with the disease, but eventually most of them die of it. Usually these tumors are resistant to radiation and they do not take up I^{131} .

Papillary carcinomas are the commonest cancers of the thyroid and the most favorable from the standpoint of cure. They are the kind of cancer in which treatment makes the most difference in the rate of cure. In papillary cancer, the outcome depends largely on the completeness with which the primary tumor and the lymph nodes to which it has metastasized are removed.

The manner in which the operation for papillary carcinoma of the thyroid should be done is a controversial issue. Some advocate use of the conventional neck dissection which is commonly applied to cancers metastatic from the oral cavity. Others believe, with good reason, that sacrifice of the stern-

ocleidomastoid muscle, which is almost never invaded by tumor, is a quite unnecessary mutilation and contributes nothing to the curability of the cancer. All agree that the operation should consist of complete removal of the affected lobe and isthmus. In patients in whom there is bilateral involvement, complete thyroidectomy should be performed; the surgeon should not grasp the tumor roughly, put clamps on it or cut into it. The neck should be completely explored on the affected side, especially behind the carotid vessels, in the posterior triangle, in the nodes in the midline above the isthmus, in the superior mediastinum on the contralateral side and especially in the chain of nodes which lies behind the thyroid along the trachea and around the recurrent laryngeal nerve. Usually this exploration can be done and all involved lymph node groups can be removed through a high, wide thyroidectomy incision with division of the strap muscles. Sometimes an anterior sternocleidomastoid incision must be employed. Since most of the patients with this disease are young women in their teens or twenties, the cosmetic aspects of the operation are important.

Following conservative operations, over 90 per cent of all patients with papillary carcinoma can be classified in the group of five-year cures. No better results have been reported following the more radical procedures. In children under ten years of age, and in men over fifty, the disease seems to be more malignant than in persons in the intervening years. Sometimes in these age groups, the cancer metastasizes to lung or to bone. When it does, radioactive iodine can be tried, but, before the tumor will take up I^{131} , all of the normal thyroid tissue must be removed or destroyed. When this is done, myxedema may ensue and, this in turn, by increasing output of thyroid-stimulating hormone, may result in rapid progress of the metastases and early death. If the cancer does not take up radioactive iodine, it is important to keep the period of thyroid deficiency to a minimum, and to start full replacement therapy with desiccated thyroid as early as possible. Often, in response to suppression of TSH by feeding thyroid, the tumor will regress or at least fail to grow.

USES OF DESICCATED THYROID

The development of multinodular goiter, struma lymphomatosa and perhaps of papillary carcinoma of the thyroid appears to be wholly or in part dependent upon the thy-

roid-stimulating hormone of the pituitary. If large doses of desiccated thyroid are given, the thyroid-stimulating hormone is suppressed, the lymphoid types of thyroiditis shrink or disappear, thyroid nodules often get smaller and some papillary cancers of the thyroid regress.

Thyroid feeding is tolerated well. In doses up to 3 grains daily, it does not cause a permanent increase in metabolism and it gives no symptoms. All that happens is that the thyroid stops making thyroid hormone. The gland is put at rest.

If thyroid strain causes many of the pathologic changes of the thyroid gland, there is no reason why these changes should not be treated by giving desiccated thyroid and relieving the strain. Many small goiters can be treated effectively in this way. The danger of cancer of the thyroid in these goiters is slight. If thyroid strain is relieved, the chances of preventing the development of cancer are good. In the future, the thyroid will challenge the surgeon as a problem in endocrine physiology much more often than as a subject for surgical technique.

HYPERPARATHYROIDISM

Hyperparathyroidism is a disorder characterized by an overproduction of parathyroid hormone. It may be either primary or secondary in type. The term "secondary hyperparathyroidism" is reserved for those unusual clinical disorders associated with an increased demand for parathyroid hormone. Its treatment is not surgical but rather requires a recognition of the underlying cause for the increased demand.

Primary hyperparathyroidism is a surgically curable disease. The increased production of parathyroid hormone arises either from an adenoma in one or more of the parathyroid glands, from diffuse hypertrophy or hyperplasia of all the parathyroid glands or from carcinoma of one or more glands. The majority of cases are produced by a single adenoma located in one of the two lower parathyroids, only 16 per cent arising in the upper two glands. Multiple parathyroid adenomas occur in about 6 per cent of the subjects. Aberrant tumors occur in about 10 per cent. Among these the mediastinum is the most frequent site (63 per cent); other aberrant tumors may be located behind the esophagus or trachea or within the thyroid gland.

The parathyroid glands play an important role in the regulation of calcium and phosphorus metabolism. One of the principal

actions of parathyroid hormone is the regulation of phosphorus excretion in the urine. Following the administration of parathyroid hormone, prompt increase in phosphate excretion occurs and is of sufficient intensity to lower the serum phosphorus concentration. Continued administration is followed by a rise in serum calcium to levels above normal, with an eventual increased excretion of calcium in the urine. Prolonged parathyroid hormone intoxication, as seen in primary hyperparathyroidism, is thus characterized by hyperphosphaturia, hypophosphatemia, hypercalcemia and hypercalciuria. It is important to realize that the calcium fraction which is altered in the blood by parathyroid hormone is the ionized fraction and not the calcium attached to protein and largely to albumin. In making a critical evaluation of serum calcium levels, an estimate of serum proteins is therefore necessary.

The alterations in calcium and phosphorus metabolism enumerated may have profound effects. The high levels of serum calcium may lead to impairment in renal function by the production either of renal calculi or of nephrocalcinosis. An increased excretion of water to aid in the elimination of the excessive calcium load leads to polyuria and polydipsia, which at times are sufficiently intense to simulate diabetes insipidus. The urine excreted is often of low pH and low specific gravity. The hypercalciuria leads to a negative calcium balance, which in turn leads to skeletal decalcification, but it is minimized in those individuals who are milk drinkers.

The symptoms and signs in hyperparathyroidism are variable but may be divided into three categories: those due to associated bone disease, those due to associated urinary tract disease and those due to the high serum calcium level.

Bone disease occurs in only about 35 per cent of all patients. The bone changes consist of generalized decalcification with superimposed tumors and cysts. These changes are called osteitis fibrosa cystica generalisata of von Recklinghausen. The bone tumors consist of solid masses of soft tissue without bone, composed of osteoblasts and osteoclasts, and the supporting cells of the bone marrow. The cysts are filled with fluid and lined with fibrous tissue.

The early symptoms of the bone disease vary from indefinite pain to bone tenderness which often simulates arthritis or neuritis. Bowing of the long bones, deformities of

the pelvis, decrease in stature from deformed vertebrae and multiple fractures can occur. The bone tumors are often diagnosed as benign giant cell tumors and occasionally are incorrectly regarded as malignant. Areas of predilection for such tumors are the jaws, metacarpals, metatarsals and the ends of long bones.

Polyuria and polydipsia commonly accompany the hypercalciuria and the phosphaturia. Renal calculi occur with far greater frequency than does bone disease, and either renal calculi or reduced kidney function is present in about 75 per cent of all subjects of hyperparathyroidism. The kidney stones are composed of either calcium phosphate or, if superimposed infection is present, a mixture of magnesium ammonium phosphate and calcium phosphate.

A serious renal complication is nephrocalcinosis, a deposition of calcium within the collecting tubules of the kidneys. In this condition, the renal tubules become plugged with calcium casts. When the condition is advanced, some degree of urea retention may occur and both the low serum phosphorus and the high urine calcium characteristic of hyperparathyroidism are obscured by the renal failure.

Hypercalcemia can be associated with other symptoms besides those already mentioned. Anorexia, nausea and vomiting may dominate the clinical picture sufficiently to simulate the symptoms of duodenal ulcer. Calcium deposition may occur in the deep conjunctiva of the palpebral fissure and may be seen under the slit lamp. Marked hypotonicity of skeletal and visceral muscles may occur with profound generalized muscular weakness, hypotonicity, absence of deep tendon reflexes and intractable constipation. The electrocardiogram may show shortening of the Q-T interval. The low serum phosphorus levels of hyperparathyroidism do not produce symptoms. They are, however, the most important single finding of diagnostic importance. The diagnosis of primary hyperparathyroidism offers considerable difficulty because attention usually is attracted by the complications produced by the disease rather than by the true underlying cause. The diagnosis depends chiefly upon indirect evidence and upon the physician's index of suspicion. Integration among history and clinical, laboratory and x-ray findings is necessary for final diagnosis.

The hypercalciuria can be confirmed by the quantitative determination of calcium excretion in the urine on a twenty-four hour

basis and after three days on a low calcium (Aub) diet. Calcium loss per twenty-four hours in excess of 200 mg. is indicative of hypercalciuria.

The alkaline phosphatase value is of no aid in the diagnosis of hyperparathyroidism and is never elevated except in those instances where the skeleton is involved. It is a good index of the degree of skeletal involvement. Patients with an elevated alkaline phosphatase value and extensive bone disease are particularly prone to develop postoperative tetany which may require intensive medical therapy until the bones are healed. The treatment of such tetany is identical to the treatment of postoperative tetany following thyroidectomy and consists of the oral administration of calcium lactate powder, 3 to 10 drachms per day, and at times the addition of vitamin D, 50 to 300,000 units per day, or Hytakerol, 5 to 30 drops per day. Parathormone, 1 cc. once or twice daily, may be given for acute attacks, but antihormones form quickly and limit its usefulness. The use of intravenous calcium is more practicable and it can be given as a 10 per cent solution of calcium gluconate in doses of 10 cc., repeated as often as is necessary for symptomatic relief.

X-ray study may be of value in contributing to the diagnosis of hyperparathyroidism by the demonstration either of kidney stones or one of the bone defects previously mentioned. One additional x-ray finding consists of the demonstration of the disappearance of the lamina dura (pendental membrane) around the teeth. When the lamina dura is decalcified wholly or in part, it is highly indicative of hyperparathyroidism.

The diagnosis of hyperparathyroidism depends upon indirect evidence obtained from a variety of sources. It is to be remembered that mild degrees of hyperparathyroidism

may be most difficult to recognize and require periodic observation. The association of the symptoms, the physical signs and the laboratory and x-ray findings leads to a high degree of accuracy in clinical diagnosis. Occasional cases are encountered in which doubt exists and a tumor can be proved to be present or absent only by appropriate surgical exploration. Above all, it is important to remember that it is possible for serious hyperparathyroidism to exist in the presence of normal total serum calcium levels.

When a parathyroid tumor is found, it is imperative that it be removed completely with the capsule intact. Patients have been reported in whom these tumors have been ruptured during their removal, have implanted themselves in the wound and caused fatal recurrences or metastases.

THE BREASTS

By IAN MACDONALD, M.D.

IAN MACDONALD is a Canadian by birth, was educated at McGill University and has had an interest in the pathology of tumors, particularly cancer, throughout his medical career. He has the quality of combining an exacting biostatistical and scientific attitude with the surgeon's desire for utilizing every possible therapeutic approach to the cure of cancer.

INTRODUCTION

Although the human mammary gland is subject to a variety of pathologic processes, there is no other anatomic site of comparable importance in which the problems of hyperplasia and neoplasia outrank all others to an almost exclusive degree. This statement acquires justification from the prognostic implications apparent in comparing all other mammary disorders with those of neoplastic nature, for only in this latter group, under modern circumstances, is the patient's life in jeopardy.

Numerically, too, the lesions representing states of abnormal hyperplasia and neoplasia are of overwhelming importance, for almost 95 of every 100 mammary lesions will be one of the diagnostic "big three":

1. Some phase of the heterogeneous manifestations of abnormality in the hyperplasia-involution cycle or so-called *cystic disease*.

2. The most common by far of the benign neoplasms of the breast, *fibroadenoma*.

3. The one group of lesions with lethal potential, generically designated as *cancer*. This term includes malignant neoplasms of epithelial origin, or *carcinoma*, as well as unusual instances of sarcoma.

The malignant and benign neoplasms both have as their only reliable and earliest

symptom and sign the presence of a three-dimensional or space-occupying tumor in the breast. Unfortunately, some non-neoplastic lesions of the breast also produce space-occupying lumps, or tumors, in the general sense of the word. On the other hand, a majority of patients with "cystic" disease of the breast present local indurative changes of varying degree and extent, but separable by competent physical examination from those due to genuine or space-occupying tumors.

Thus, the most important single problem to be determined in the woman whose complaint is related to the breast, or even in asymptomatic patients on physical examination, becomes obvious. Is there discoverable a genuine, space-occupying tumor? If so, the physician must take steps toward securing an exact, which is to say, histologic, diagnosis. For this dictum there is but one reason, only by the histologic method is it possible to determine whether the true lump in the breast is neoplastic and whether benign or malignant in nature.

No other maneuvers ancillary to careful physical examination are reliable. Thus the entire responsibility of decision for or against diagnostic action must be based on the physician's ability to develop a *tactus*

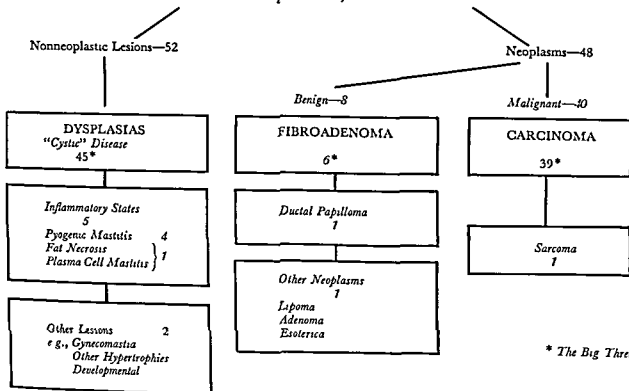

cruditus in examination of the breasts. Development of skill in tactile examination of the breasts should be regarded as an absolute requirement for every clinician who undertakes responsibility in this respect. Failure to achieve such skill and failure to perform a meticulous, orderly examination are responsible for the lack of more effective or even lifesaving treatment at a favorable stage of the disease in some patients with cancer of the breast. On the other hand, the inability of the clinician properly to evaluate changes in mammary texture and consistency leads to many unnecessary exploratory procedures for biopsy of areas lacking any evidence of neoplastic change.

Efforts of the American Cancer Society in public education are alerting many more thousands of women each year to the value of periodic examination for the early detection of "a lump or thickening" in the breast. Recommended are self-examination at monthly intervals by a uniform method and examination by a physician at twice-yearly intervals after the woman has reached the age of 35 years. As would be expected, most of the "lumps" detected by self-examination are not three-dimensional tumors; the majority represent changes in consistency associated with "cystic" disease, areas of premenstrual hyperplasia, cutaneous adnexal

structures, underlying rib or cartilage or the normal axillary prolongation of the mammary gland. Only one of approximately 1000 adult women doing self-examination regularly for one year will discover a true lump which proves to be a cancer. In forty years a total of forty cancers per thousand would have been discovered.

Balanced against this small yield of malignant tumors, presumably discovered when smaller in size than if accidentally found, is the hazard of unnecessary surgical procedures by inexperienced clinicians. It becomes an urgent necessity for physicians to resist the anxiety engendered by the self-discovered "tumor" and, if the criteria for biopsy are not present, to guide the program of self-examination by careful supervision, observation and reassurance. The extremes of conciliation by incision and alienation by indifference are a disservice to the patient and a reflection on the profession. Even though the net improvement in curability achieved by periodic examination may be small in the face of the natural history of cancer of the breast, every physician has an obligation to contribute as best he can to the total effort. The potential impact is that of effective treatment at an earlier stage of the disease in more patients, which can be expressed in terms of clinical control for five

Table 1. Approximate Incidence of Lesions of Breast for Each 100 Patients Whose Complaint Is "of the Breast"

* The Big Three

to ten years for several additional thousands of women annually in the United States alone.

In any unselected group of women whose presenting complaint is of the breast, a distinct majority will be found to have some phase of "cystic" disease, cancer being next most common, followed by fibroadenoma. The small remainder not included in the "big three" constitute the unusual and esoteric mammary lesions (Table 1) The approximate distribution of lesions in one individual's practice is:

	TOTAL	PER CENT
"Cystic" disease	609	45
Cancer	537	40
Fibroadenoma	88	7
All other lesions	111	8

About one-third of patients with "cystic" disease will have developed some phase of the process resulting in a three-dimensional tumor (gross cysts, sclerosing reaction or persistent focal hyperplasia) Some of the "other lesions" are also space-occupying lesions. Thus, about six out of ten women with complaints referable to the breast, at least in a specialized type of practice, have presented true, mensurable tumors requiring surgical, diagnostic action. Of the patients requiring such action, not more than 50 per cent should prove to have "cystic" disease. When the diagnosis of "cystic" disease in biopsy tissue exceeds 60 per cent of all biopsies of the breast, such excess indicates the inability of the clinician to differentiate between true and false lumps, and is a reliable measure of the frequency of unnecessary surgical explorations in the experience of the individual surgeon or of the institution.

This introductory emphasis on the problems of clinical and surgical-pathologic diagnosis is an essential preface, for each individual patient should be considered in relation to established diagnostic probabilities. The problems involved are of paramount importance, for the breast continues to be the most common organ site of cancer in the adult female population of the United States. Efficient clinical performance is in direct ratio to the relative number of biopsy tissues diagnosed as lesions other than "cystic" disease.

To achieve reasonable accuracy in the selection of mammary lesions requiring biopsy, the clinician should have a knowledge of anatomic variations, physiologic (endocrine) factors, the variegated dys-

plasias ("cystic" disease) and the natural history of certain hyperplastic states.

ANATOMY

In the female, each mammary gland rests upon the fascia of the pectoralis major muscle. The peripheral limits of the gland are variable from one patient to another, but ordinarily breast tissue extends almost to the midline over the sternum, to the anterior axillary line laterally, and from the level of the second rib above to about the sixth rib inferiorly in a horizontal line drawn through the nipple. The greatest variation in peripheral extension occurs in the axillary area. Most often there is a blunted, narrow extension of the gland which may still lie on the fascia over the converging fibers of the pectoralis major, while in other instances this so-called axillary tail of the breast is found below or posterior to the pectoralis major muscle in the lower third of the axilla. In unusual instances, the axillary tail may be a prolongation extending into the middle third of the axilla and lying in contact with the pectoralis minor muscle or the intercostal muscles. In such abnormal axillary extensions, the indurative changes of "cystic" disease may occur, as well as actual neoplasms, and in such instances their origin in mammary tissue may be unrecognized. Still more unusual are the instances of supernumerary foci of mammary glandular tissue, most often without corresponding nipples, which may occur in the axillary area as well as in the anterior axillary line and also below and medial to the normal breast.

Supernumerary foci of mammary tissue may exhibit the cyclic changes which characterize the physiologic response of the breasts to hormonal stimulation.

The superficial fascia of the breasts is attached to the skin, a fact of extraordinary clinical importance. A layer of fat surrounds the gland except in the area of the nipple and areola. The thickness of the subcutaneous fat is highly variable. In thin women with underdeveloped breasts, the subcutaneous fat layer may be almost nonexistent so that the reflection of skin from the breast during radical mastectomy requires a meticulous peripheral dissection of extremely thin skin flaps. With increasing obesity, or with fatty replacement of mammary parenchyma, the thickness of the subcutaneous fatty layer correspondingly increases. The anterior surface of the gland is irregular owing to the lobulations formed by the deep

attachment of fibrous septa, the eponymic designation of which is Cooper's ligaments, which run between the superficial and deep fascia.

The mammary gland is made up of ten or twelve to twenty glandular lobes drained by an equal number of tortuous ducts which dilate close to the nipple to form ampullae, and finally divide into minute ducts ending in small openings in the nipples. Each of the orifices in the nipple corresponds roughly to a truncated segment of breast which it drains, a fact of importance in the investigation of bleeding or other discharge from the nipple.

The parenchyma of the breast is composed of two types of epithelium, acinar or secretory, and ductal. Both have a double fibrous covering, the inner periductal or periacinar layer and an outer layer of perilobular connective tissue. The acinar components of the breast are highly variable in quantity during puberty, the reproductive years and even after the climacteric, conditioned upon response to hormonal stimulation. The ductal components are less variable in quantity after maturation except in the instance of pregnancy and lactation. The acinar epithelium is cuboidal in shape while the epithelium of the ducts is columnar.

In men and in prepubertal females, the gland is rudimentary with only a few short ducts and ordinarily without genuinely developed acini.

Cutaneous Lymphatics. There is a continuous intercommunicating network of lymphatics over the entire surface of the chest, neck and abdomen. By this mechanism, the subcutaneous lymphatics over one breast

communicate with those of the opposite gland. There are even some lymphatics originating under the skin which drain into the contralateral axillary nodes. For each breast there is a collecting network of lymphatics under and adjacent to the areola.

Intramammary Lymphatics. The lymphatics originating within the breast drain by the following pathways (Fig. 1):

1. A few will follow the ducts and terminate in the subareolar lymphatic network mentioned above, mainly from the central area.

2. The principal route is the axillary pathway coming from all parts of the gland and draining directly to the central axillary nodes, the nodes around the axillary vein or the subscapular group. There is also drainage to intercostal nodes in the second and third intercostal spaces.

3. A transpectoral pathway penetrating the pectoralis major muscle and ending in the supraclavicular nodes, although some may drain into infraclavicular nodes behind the pectoralis minor muscle.

4. The internal mammary pathway which passes through the pectoralis major and intercostal muscles adjacent to the sternum and drains into the nodes of the internal mammary chain, lying deep to the costal cartilages and surrounding the internal mammary blood vessels.

PHYSIOLOGY

The hormonal control of the parenchyma of the breast has become well established, both by experimental studies in animals and biopsies from human mammary glands during various phases of the menstrual cycle and during pregnancy and lactation. The estrogenic hormones during the first half of each menstrual cycle produce ductal hyperplasia, and at the same time sensitize the acinar epithelium for the action of progesterone during the second half of the cycle, the latter hormone producing acinar hyperplasia. In the absence of preliminary sensitization of the acinar components by estrogens, there is very little hyperplastic response from the administration of progesterone alone, as shown in oophorectomized animals.

These cyclic changes of ductal and acinar hyperplasia, with some hypertrophy, occur in irregular focal fashion, although the degree and extent of response each month is highly variable from one woman to another. With the onset of menstruation, there normally occur involutionary changes in the

Figure 1. Lymphatics of the breast 1, subareolar, 2, axillary, 3, transpectoral, 4, internal mammary.

areas which have been so stimulated to hyperplasia, only to be succeeded promptly by the same cycle of hyperplasia of ducts and then of acini in other segments of the breast. If these repetitive cycles of response in the parenchymal (target) tissue are unattended by abnormalities throughout the reproductive years, there is little in the way of symptomatology except a feeling of premenstrual fullness or, at the most, a slight soreness usually limited to small areas in the breast. Distinct abnormalities in this hyperplasia-involution cycle are interpreted as the basic mechanism in the production of so-called cystic disease.

During pregnancy the hypertrophic and hyperplastic changes are the same as those during a menstrual cycle except on a grandiose scale. During the first four to five months of pregnancy, the changes are largely in the ductal system, while in the latter part of pregnancy, particularly in the last three months, the dominant response is that of tremendous acinar overgrowth. The final phase is that of secretory response by the acinar epithelium, with prelacteal exudate draining into the ducts and constituting the material known as colostrum. After delivery, and principally under the influence of a hormone from the anterior pituitary, prolactin, the acinar components rapidly reach a peak of secretory activity and distention to produce the fully lactating breast.

The estrogenic steroids and progesterone concerned in the cyclic changes are, of course, elaborated by the ovaries, under the control of the corresponding gonadotropic hormones of the anterior pituitary. Following the climacteric, there is evidence that in some women the adrenal cortices take over the function of production of estrogenic steroids and, in occasional instances, such levels of estrogen production may approach those of the woman with an active follicular-luteal mechanism. This evidence seems to account satisfactorily for the occasional postmenopausal woman who continues to have symptoms of mammary congestion and soreness and objective findings similar to those patients who suffer from abnormalities of the hyperplasia-involution cycle in earlier years.

With these unusual exceptions, the parenchyma of the breast undergoes a slow progressive involution over a period of five or more years following the onset of the climacteric, with atrophy and replacement of parenchyma by fatty infiltration.

The preceding description of interplay of certain steroid hormones on the mammary epithelium is, of course, a working skeletonization of existing knowledge and is dependent upon a considerably more complex endocrine background involving the pituitary-thyroid-adrenal axis. Some experimental work, for example, indicates that in hypothyroidism estrogenic stimulation of the breast produces a cystic type of hyperplasia. In some species of animals, after castration, stimulation with estrogen alone will produce considerable acinar hyperplasia which is also of cystic type, and in which frequent papillomatous epithelial lesions of hyperplasia occur, while with the concomitant administration of progesterone such cystic and papillary changes do not occur. Although experimental, these are findings which one may relate by inference to some of the abnormalities of hyperplasia-involution in the human being.

EXAMINATION OF THE BREASTS

It is of primary importance that a woman whose complaints are related to the breast should have a general physical examination, unless she has had one performed by a competent physician in the preceding three months. Pelvic examination is essential because of the not-infrequent association of gynecologic pathologic states with breast lesions, particularly with "cystic" disease. In functional disturbances of the breast, stigmata of endocrine dysplasia should be searched for, such as hirsutism, abnormal deposits of fat and uterine hypoplasia, as well as indications of hypothyroidism. Should the patient have a three-dimensional tumor which may be carcinoma, methodical examination of such accessible areas as may harbor metastatic foci is essential. If a general physical examination is not to be done, the patient should at least be undressed to the waist and draped with a sheet or a gown.

Preliminary examination should be done with the patient sitting comfortably but erect on the end of the examining table, with the hands resting in the lap and the legs uncrossed. With the patient in this position, the breasts should be inspected for equality of size and similarity of contour, for disparity in the appearance of the nipples and variation in level of the nipples. It should be obvious that this must be accomplished in a good light.

Approximately one-fourth of women have some minor degree of inequality in the size

of the breasts of developmental nature, while in a very occasional woman there may be an obvious unilateral hypertrophy usually unrelated to pregnancy or lactation. It should also be noted that in women who have any degree of scoliosis there will be a distinct lack of symmetry in the breasts, the breast on the side of the convexity of the scoliosis being higher than the opposite breast and the level of the nipples correspondingly altered (Fig. 2).

The color and the consistency of the skin over the breasts should be carefully noted, particularly for areas of erythema or edema. Retraction of the skin due to carcinoma will rarely be noted in this position, except in the instance of an advanced lesion. In fact, distinct retraction of the skin demonstrable with any method of examination is usually an indication of lymphatic permeation and a relatively advanced lesion.

The patient should now be asked to bend forward and thus note whether in a dependent position there is lack of mobility of either breast, alteration in the relative nipple position or evidence of skin retraction in any area.

With the patient sitting straight again, and the arms still adducted and without tension on the pectoral fascia, the axillary folds, the supraclavicular and cervical areas and shoulders should be inspected for any evidence of asymmetry.

Figure 2. Normal asymmetrical breasts due to scoliosis.

By gentle palpation, the neck on both sides and, particularly, the supraclavicular areas should be searched for abnormal nodes. The thyroid should be palpated for abnormal enlargement or displacement. Next, the infraclavicular area should be palpated for possible nodes.

The axillary area on each side should be palpated for lymphadenopathy, the patient's forearm resting on the opposite forearm of the examiner in such a fashion that the patient's upper extremity is entirely relaxed. With the flat of the fingers and beginning at the axillary apex, the axilla is gently palpated. Special attention should be given to the so-called retropectoral area, where nodes lying behind the converging fibers of the pectoralis major muscle may be palpated.

Palpation of the breast itself with the patient in the sitting position yields much less information than that accomplished with the patient in the supine position, except in the central third of the breast. In the latter area, the nipple and areola are carefully examined for indurative changes. With one hand supporting the breast from below, and the other palpating gently from above, abnormality in the ductal system adjacent to the areola may often be detected. The surface of the nipple and areola should be carefully examined for evidences of scaling or erosion, even though of minute degree.

If there seems to be any disparity in the size of the arms, the circumference of each arm should be measured at the same distance from the acromial process on each side, the 5-inch level being practicable.

Still in the sitting position, the patient should now be asked to abduct the arms to a 90-degree angle. The inspection is again made for inequalities in the level of the nipples and for possible areas of skin retraction which may now be apparent with the pectoralis fascia under tension, particularly in lesions located in the upper outer quadrant of the breast.

With the patient in the supine position, each breast is methodically palpated, first with the arm in adduction and then in sharp abduction. In some women, particularly those with bulky breasts, this part of the examination may be facilitated by placing a pillow under the scapular area of the side being examined, particularly to obtain better palpation of the lateral portion and axillary tail of the breast. All of this examination should be by the flat hand, remembering that the maximum tactile sensitivity is located in the distal two-thirds of the flexor

Figure 3 The lesions of both A and B may resemble lumps by finger palpation with the patient in the sitting position. By flat-hand palpation with the patient in the supine position, the more advanced lesion in A is detected as a true lump, that in B a pseudolump. C, Soft, normal breast lobules not palpable. D, Few days' premenstrual breast is fuller, more dense, vague outline of lobules

surfaces of the fingers. Finger-point examination has no place in this examination, for it will frequently produce the illusion of a three-dimensional tumor when none is actually present (Fig. 3 A and B). In order to accomplish systematic palpation of the entire breast, one should begin at some arbitrary axis and, by flat-hand palpation around the circumference of the breast, determine variations in consistency and search for space-occupying lumps. The area of the axillary tail of the breast should be examined separately and special attention given to the inframammary fold with upward traction on the breast during examination of the latter area.

As experience is gained, one will be able

to differentiate between varying degrees of consistency in various types of normal breasts. In Figure 3 C, for example, is illustrated a soft normal breast in the first half of the menstrual cycle with the lobules not palpable. In D during the few days premenstrual, the breast is fuller, more dense and careful palpation may suggest the vague outline of lobules throughout the breast. Illustrated in Figure 4 E is another type of normal breast with considerably different consistency in which, during the early part of the cycle, the lobules are distinctly palpable in the peripheral two-thirds of the breast, while in the central third vaguely outlined radiating areas may suggest the ductal structure. In such a breast,

the palpable lobular and ductal architecture will have become considerably exaggerated in the premenstrual phase (Fig. 4 F). The lobules are now palpable to a more distinct degree and the radiating ductal system may also be more apparent in the form of linear, irregular or even slightly beadlike areas. In this sort of breast it is possible by finger-point palpation, and even more by palpation between two sets of opposing fingers, to obtain the sensation of a tumor in one of these well-developed lobular areas. When such an area is gently palpated with the flat of the fingers, the pseudotumor disappears, blending into the adjacent breast tissues.

In these schematic representations, there is implied a uniformity of palpable lobules and ducts along with their premenstrual exaggeration. In fact, the distribution of such palpable normal lobules, either in the resting or hyperplastic stage, usually is extremely irregular.

Represented in Figure 5 are focal areas of persistent abnormal acinar hyperplasia, one represented in the right breast (G), where the lobules are diffusely palpable, and in the left (H), in a soft breast with impalpable lobules. It is possible to interpret these lesions as a lump by fingertip palpation, particularly with the patient in the sitting position. On flat-hand palpation with the patient in the supine position, they should be apparent only as abnormally indurated areas without the circumscription or substance of a space-occupying tumor.

More advanced abnormalities of the hyperplasia-involution cycle are portrayed in the lower part of Figure 5. Represented in the left breast (J) are an area of abnormal hyperplasia now large enough in extent to have become a three-dimensional, vaguely circumscribed tumor, another area just above the areola which may also be a three-dimensional lump, while the lesser areas indicate indurative changes without the substance of a genuine lump. In the right breast (I) are represented various degrees of the actual cystic phase of "cystic" disease, with two gross cysts in the upper hemisphere constituting three-dimensional tumors, while in the lower hemisphere are two small cysts which would constitute distinct nodules only if there was sufficient tension of contained fluid within the cyst. The most medial nodule represents a combination of the cystic and hyperplastic phases of "cystic" disease.

If a three-dimensional tumor has been

satisfactorily outlined, its location should be indicated accurately on a diagrammatic sketch on the patient's record. This may be done either on a free-hand sketch of the breast and adjacent axillary and supraclavicular areas or a stamped outline. The dimensions of the tumor should be determined as accurately as possible by measurement with a ruler and written on the diagram. Also shown should be the location and approximate size of enlarged regional lymph nodes, if found, or the absence of lymphadenopathy should be indicated. The sketching in of the tumor can also indicate whether it is round or ovoid or irregular in outline.

If possible, one should determine whether the surface of the tumor seems smooth or irregular, usually possible in a patient with small breasts or in tumors superficially located. The degree of mobility, or its impairment in relation to adjacent breast tissue, deserves description. If the tumor is deeply located or bulky in size, the presence or absence of attachment to the pectoral fascia or to the chest wall should be determined and noted. Such a combination of schematic representation and brief description of essential features is informative and accurate, saves time and space and is of particular importance in those patients requiring subsequent observation of questionable lesions.

In the diagnosis of small carcinomas of the breast, significant changes in the over-

Figure 4 E, Early part of cycle. Lobules palpable in peripheral two-thirds, vaguely outlined in central one-third. Radiating areas may suggest ductal structure. F, Premenstrual phase. Lobules palpable to more distinct degree. Radiating ductal structure more apparent.

Figure 5. Advanced abnormalities of the hyperplasia-involution cycle G, Right breast lobules are diffusely palpable. H, Left breast soft with impalpable lobules I, Right breast Two gross cysts in upper hemisphere constituting three-dimensional tumors Lower hemisphere, Two small cysts which would constitute distinct nodules only if there is sufficient tension of fluid within The most medial nodule represents combination of cystic and hyperplastic phases Left breast An area of abnormal hyperplasia now large enough to be a three-dimensional, vaguely circumscribed tumor Another area above areola may also be a three-dimensional tumor. Lesser areas indicate indurative changes without substance of genuine lump

lying skin usually are so minimal as to be almost subtle. These include an evident impairment of elasticity of the skin overlying the tumor or minor degrees of skin attachment. Such changes may become evident only on changing position of the breast or altering the degree of tension on the pectoral fascia, as already described in the maneuvers of abduction of the arm and forward bending in the sitting patient. Skin tension

over the suspected area is reduced best when the examiner, with the patient lying supine, gently displaces the breast upward, laterally or medially. Depending on the location of the tumor, the skin may remain taut or slightly depressed over a carcinoma of small size Many times, decreased mobility of the skin is best seen with a strong source of illumination lighting the area under investigation tangentially. Occasionally, too,

inspection under magnification of two or three diameters may bring out alterations not otherwise seen.

Changes more obvious than these, such as obvious areas of retracted skin, genuine retraction of the nipple, ulceration of the nipple, distinct erythema or lymphedema, are all signs of advanced disease of the breast, whether inflammatory or neoplastic. The physical signs of early disease of the breast are detected only by exact and meticulous methods of examination and are more suitable for schematic than photographic illustration. Lesions of the breast which are photogenic are so advanced as to be clinically obvious.

Too much emphasis cannot be placed upon development of perceptiveness in the digital, tactile end-organs to the point of performing a sort of projected stereognostic function. Such perceptiveness is epicritic, never protopathic. Until such time as more exact methods may be developed, the physician's skill in examination is the only approach to detection of neoplasms of limited, local extent.

Transillumination of the breast is more impressive to the patient than it is informative to the examiner. After having had a considerable vogue some years ago it is now used by very few clinicians of experience. *Roentgenograms* of the breast for soft tissue detail are informative in some instances but can be misleading. Their net value does not seem commensurate with the effort and expense required. Malignant neoplasms are almost always associated with a distinct increase in vascularity of the affected breast and *infrared photographs* usually demonstrate rather well this circulatory phenomenon. Malignant epithelial cells in the breast have a somewhat higher uptake of *radioactive phosphorus* than do non-neoplastic cells, but unfortunately the disparity in uptake is not consistently evident until a carcinoma of the breast is of such size as to be clinically obvious.

For the woman who has a *discharge from the nipple*, the first approach should be routine examination in search of a space-occupying tumor. If none is found, the examination is directed toward localization of the duct or ducts from which the discharge originates. In some instances, the patient herself may have discovered a pressure point. If there has been recent bleeding, inspection of the nipple under magnification may reveal an orifice containing dried blood. The most important part of the examination

is *radial stroking* of the breast with a fingertip, with the patient supine, from the periphery toward the areola, repeating the process in clockwise fashion over twelve or more circumferential segments. If this maneuver does not localize the ductal area of origin, it may be repeated with the patient in the sitting position, although the results are not as reliable. If a pressure point is successfully located, it should be marked on the skin with the patient supine and accurately located on the diagram. The location of the ductal orifice on the nipple through which the discharge exudes should also be indicated. It is advisable to repeat the examination five to seven days later to verify the apparent ductal source of discharge.

The procedure described for breast examination represents a preference. Both the techniques employed and the sequence of the examination vary from one physician to another. The essential objective is for the clinician to have an orderly pattern of procedure in examination of the breasts and adjacent regions, with such attention to detail as to accomplish a thorough survey in every patient.

Self-Examination of the Breasts. As indicated, one phase of the program of public education directed toward discovery of cancer at an earlier stage is the recommendation that women undertake monthly self-examination of the breasts, particularly after the age of thirty years. While some physicians are critical, there are a number of valid reasons for professional support of such an effort. For obvious psychologic reasons, no more than a small minority of the population will ever pursue such a program consistently, but even for this fraction it is less than rational to consider the possibility of monthly medical examination.

A recommended technique of self-examination of the breast is well portrayed in a cinematic film of the same title available from the American Cancer Society. However, a certain number of women request instruction in the technique of self-examination from their physicians. The recommended procedure involves self-inspection of the breasts for the same changes described above. This is done with the woman sitting in front of a mirror with adequate illumination, sitting erect and with the arms adducted. Self-palpation of each breast is done in the supine position with the arm abducted, and with a small pillow under the scapular area of the side being examined.

Methodical circumferential palpation is done with the flat of the fingers of the opposite hand

Obviously, the initial achievement of importance is for the woman to become acquainted with mammary texture and consistency and frequently with the indurative abnormalities of "cystic" disease already present. The physician can do much to facilitate this learning process at the time of initial instruction. After several months of experience, many women become able to detect new areas of indurative change, and sometimes discover space-occupying tumors when they are as small as 1 cm in diameter.

DEVELOPMENTAL ANOMALIES

The least uncommon of the unusual developmental disorders is that of supernumerary nipples or breasts. Practically all such instances of ectopic development occur along the primitive milk line, which extends from the axilla downward across the nipple and thence downward and slightly medially to a point just below the inner third of the inguinal area. The great majority of supernumerary foci occur either in the area above and lateral or below the breast proper. Racial determinism is a factor of importance in location, frequency and relative incidence by sex. A Japanese study showed 15 per cent of males and 5 per cent of females with accessory nipples, while a report from a review of 20,000 school children in England demonstrated an incidence of only 0.4 per cent. The ectopic focus may be constituted of nipple alone, of parenchymatous mammary tissue in varying stages of development or more rarely both may be present. From a standpoint of clinical importance, the most confusing ectopic foci are those of genuinely separate axillary mammary tissue. Many of the so-called supernumerary axillary foci are simply abnormal prolongations of the axillary tail of the breast. The indicated treatment is surgical excision for cosmetic or diagnostic reasons, or both. The necessity for excision in the axillary area is more urgent, as carcinoma has been known to develop in axillary sites of ectopia.

Complete absence of one or both breasts or segmental failure of development of a breast is so rare that it is unknown to most clinicians. Minor degrees of disparity of size of the breasts is usually of developmental origin, while distinct hypertrophy is more reasonably ascribed to postnatal physiologic disturbances.

The most common malformation of the

nipple is that of inversion. Less often, a developmental fissuring of the nipples is seen. Both of these disturbances are, with rare exceptions, bilateral. Their clinical importance is that they be historically established as of developmental origin and not confused with deformities of the nipple secondary to a pathologic process within the breast.

There is some academic justification for a belief held by some that two intramammary developmental defects may contribute to some unusual neoplasms in later life. Remnants of the nipple pouch have been noted in the area of the large ducts as late as puberty. This may be the origin of rare epidermoid cysts, with or without squamous carcinoma, and also accounts for at least some instances of Paget's carcinoma of the ducts and nipple. Since the mammary gland represents a modified sweat gland structure, remnants of the mammary buds may be associated with the occasional development of carcinoma of the breast which is of distinct sweat gland structure.

TRAUMA AND FOREIGN BODIES

The breast has a remarkable tolerance for injury and usually will achieve restitution to normal even after extensive extravasation of blood into the parenchyma, fatty and other connective tissue. The most disruptive injury, short of actual laceration, is also the most common of all, that of surgical incision for biopsy or resection. Resection is commonly followed by a period of organization ending in more or less severe fibrosis, which not uncommonly may produce a three-dimensional lump more impressive than the tumor which may have originally been present. These postsurgical sclerosing reactions usually regress slowly over a period of months, sometimes completely, sometimes leaving a focus of smooth induration under or adjacent to the scar. The most common complication of trauma, either accidental or surgical, is the formation of a hematoma. If the blood is in a fluid state and reasonably well localized, it may be aspirated through a 14-gauge needle. Collections of organizing hematoma of more than minor size require incision and evacuation of the blood clot under local anesthesia.

Occasionally suppurative infection may follow trauma, usually developing in unspirated or unevacuated areas of hemorrhage. It is of considerable importance that such areas of post-traumatic cellulitis have prompt treatment to forestall ramification of the infection. If evidence of suppuration is lack-

ing, treatment with sulfonamides or antibiotics should be instituted. If an abscess develops, prompt incision and drainage are indicated, preferably with the patient under general anesthesia to permit thorough evacuation of secondary pockets which may be present. This procedure should be followed by use of an antibiotic, or antibiotics, selected by sensitivity tests, continued for a minimum period of ten days.

A more unusual but frequently confusing complication following trauma is that of *fat necrosis*. This lesion is most apt to develop in obese patients or those with pendulous breasts. Although a history of injury is not obtained in some patients, disruption of fat cells is the mechanism by which the process is initiated. A slow aseptic saponification of fat by blood and tissue lipase develops. The lesion may vary from 1 or 2 cm. to as large as 8 cm. in diameter. The surface is firm and irregular and frequently the skin becomes attached to the tumor and even retracted, although there is seldom any retraction of the nipple. Fat necrosis can, therefore, simulate carcinoma with such exactness that this is one of the few lesions for which radical mastectomy has been done on the basis of an apparently inescapable clinical diagnosis of carcinoma. Gross examination of the cut section usually differentiates the lesion from carcinoma because of the diffuse yellowish to orange coloration and the greasy consistency. In some of the lesions, cystic degeneration develops with the formation of pools of fat which may be surrounded by foci of hemorrhage. Eventually, in cases of long duration, calcification occurs in the cystic areas. Treatment is simple excision with a margin of adjacent breast tissue. Diagnosis is readily made by frozen sections.

It is pertinent to emphasize that evidence is lacking to implicate trauma as a *causative factor in cancer of the breast*. As an exposed organ resting on the rigid thoracic cage, the breast suffers innumerable traumata during a woman's lifetime. A considerable percentage of women with cancer report prior injury to the affected breast. The breast is probably the most frequent site of cancer in which an allegation of causative trauma becomes the basis for medicolegal action. The fact is that, almost without exception, a minor injury directs attention to a preexisting lesion. While there is an imposing documentation against the thesis of trauma as a causative factor, two considerations are sufficiently convincing.

The most frequent injury to the breast, and certainly as severe as any, is incision for resection of part of the organ. There is no recorded instance of cancer developing in an operative site not previously involved by a neoplastic process. Traumatic fat necrosis, a particularly severe sequela of trauma resulting in cellular disruption, has not been a precursor of cancer in any recorded instance.

Carcinoma of the breast characteristically is a process of multicentric origin.

The most frequent *foreign body* in past years has been paraffin used for cosmetic reasons, resulting in the development of paraffinoma representing a foreign-body granulomatous reaction and producing irregular lumps which may require excision. Some of the nonabsorbable suture materials, particularly cotton, may produce foreign-body granulomas. Currently employed by some plastic surgeons, with preoccupations more esthetic than correctional, are the synthetic substances related to some of the plastic materials used by industry. Experimental evidence in animals as to their hazards is contradictory and sufficient time has not yet elapsed to assess the tolerance of human mammary tissue to these agents.

INFLAMMATORY LESIONS

Pyogenic Infections. Suppurative infections of the lactating breast, fairly frequent prior to the advent of chemotherapy, have now become unusual, although an occasional patient still progresses to the stage of abscess formation. Very occasionally, a woman with a genuinely cystic phase of dysplasia of the breast will develop a secondary infection in and around gross cysts, an inflammatory process superimposed on the dysplasia. Developing most often in long-standing cystic disease, such infections usually are low grade and slowly progressive. These rare instances represent the one situation where the old misnomer, chronic cystic mastitis, becomes an apt and accurate designation. Seldom seen are women who develop a pyogenic infection without trauma, except lactation or gross cystic changes, apparently as a result of hematogenous dissemination from some primary focus of infection, apparent or occult.

Abscesses beginning in the subareolar area and involving the central third of the breast have an extraordinary tendency to recur and to be resistant to treatment. Some of these centrally located infections seem to represent an extension of cutaneous adnexal

infections. In recurrent abscess of the breast, wide removal of the previous scar or scars, the underlying chronic abscess cavity and the adjacent ductal system should be undertaken during a period of quiescence of the infection. Such wide excisions should be performed only after repeated incision and drainage and use of antibiotics, following which the process may gradually subside over a period of months. Choice of an antibiotic agent by sensitivity tests is of great importance, the strain of *Staphylococcus pyogenes* var. *aureus* most often present is resistant to penicillin.

Irradiation has been of no value in our experience, except in occasional limited, early foci of cellulitis. In these, a tissue dosage of 300 to 450 r is adequate, divided into two or three treatments.

Tuberculosis. Tuberculosis of the breast is now an exceedingly rare disease. It is invariably either secondary to an active distant focus or from direct extension of disease in the underlying costal cage. Advanced tuberculosis of the breast is accompanied by multiple sinuses and frequently by involvement of the regional axillary nodes. Thus, the treatment is radical mastectomy.

Plasma Cell Mastitis. This rare form of mastitis usually occurs in married women under the age of forty years. The dominant symptom is pain. There is usually localized erythema overlying a poorly defined bulky mass in the breast and occasionally there is a milky discharge from the nipple. The skin may become adherent to the mass, is commonly edematous and retraction of the nipple may be present. Thus, the lesion often mimics a carcinoma of the acute or inflammatory type. Enlarged axillary lymph nodes of some size may be present. Clinicians, neglecting the confirmatory evidence of histologic diagnosis, have performed radical mastectomies for this lesion. Some of these purely inflammatory processes, perhaps most, are highly radiosensitive. When confronted by such findings in a married woman under forty years of age, with no recent history of lactation, information of diagnostic value will probably be obtained from one or more biopsies of the involved skin, including the subcutaneous tissue, and smears from the nipple discharge, if present. This can be done as an office procedure under local anesthesia. If histologic study of the material so obtained fails to show foci of carcinoma cells in the skin or subjacent tissue or in the smear, one can eliminate the

possibility of genuine inflammatory carcinoma with certainty. However, the possibility of carcinoma with erythema of overlying skin cannot be excluded. If the evidence favors the diagnosis of plasma cell mastitis, roentgen therapy in moderate dosage is advised, about 600 rads delivered in two weeks' time. This amount of irradiation over such a period usually induces complete regression of this form of mastitis. If the physical findings are not entirely consistent with this disorder, and in those patients in whom this amount of irradiation does not produce satisfactory regression within three weeks, adequate material for biopsy should be obtained by a surgical approach. Should carcinoma be demonstrated, it is usually biologically inoperable and best treated by intensive roentgen therapy.

Mammary Duct Ectasia (Comedomastitis). This process may simulate carcinoma in elderly women, to whom it is almost limited. The process is characterized by wide dilatation of the ducts, particularly of the central third of the breast, in which accumulation of fatty debris is accompanied by ductal and periductal inflammation and eventual sclerosis. With severe sclerosis, the ducts may become shortened, thus retracting the nipple so that the physical findings approximate those of subareolar carcinoma of the ducts. In the early stages, the involved ducts can be outlined as individual cirroid or vermiform structures, with little or no resemblance to a possible neoplasm. In the later stages of sclerosis, induration and nipple retraction, excision and histologic diagnosis become necessary.

It is worthy of note that all three of the inflammatory processes which may simulate cancer—fat necrosis, plasma cell mastitis and duct ectasia—are believed by some observers to be variants of the same basic disorder of ductal stasis, with trauma playing a determinant part, followed by inflammatory reaction to chemical irritants.

DISORDERS DUE TO ABNORMAL PHYSIOLOGY

Prepubertal Hyperplasia. The earliest example of hyperplasia of endocrine origin is that of *neonatal hyperplasia*. Almost one-half of infants, both male and female, exhibit a transient enlargement of the mammary disk as a result of hormonal stimulation through the placental blood. In about one of ten newborn infants, this is accompanied by a scanty secretion of thin fluid from the nip-

ples. This hyperplasia may persist for six months or more, particularly in female nursing infants.

Rare instances of mammary hyperplasia and hypertrophy during the first five years of life, or so-called precocious mammary development, are almost invariably due to hormone-producing neoplasms of the ovary, adrenal cortex or hypophysis or to hypothalamic lesions.

Later in life, and most often from the ages of eight to twelve years, unilateral hypertrophy unassociated with any recognizable endocrine abnormality is not uncommon. Such female prepubertal hypertrophy may be transient or may persist until puberty, during which period the opposite breast undergoes development equal to that of its fellow.

At the time of puberty, there are rare examples of *hypertrophy* of one breast or even of both. Attempts at control of such hypertrophic abnormalities have been unsuccessful and when they are disfiguring, appropriate plastic surgery is indicated.

Gynecomastia. Enlargement of the breast in the male, either unilateral or bilateral, is most common during the period of puberty and after the age of forty years. Gynecomastia developing during *puberty* is ordinarily transient and unilateral, with an average duration of twelve to eighteen months. It represents an adolescent, mammary dysplasia of functional type, secondary to the profound changes in steroid hormone levels characteristic of adolescence. The process may be a diffuse, slightly lumpy or even nodular enlargement of the entire gland, in which case the diagnosis is obvious. More often, however, there is a discrete tumefaction, usually subareolar in position, and the area of localized indurative change may be from one to several centimeters in diameter. The finding of a measurable lump frequently arouses such apprehension in the clinician that he performs an excision for microscopic diagnosis. No such action is necessary because malignant neoplasia in the mammary gland of the adolescent male is unknown. The differential diagnoses of remote chance in boys at this age are dermoid cyst, lipoma, hemangioma and lymphangioma. The only indication is for observation at intervals of several months. In only two instances in my experience has adolescent gynecomastia persisted and been of such degree as to require treatment, which is subcutaneous mastectomy. Attempts at control of adolescent gynecomastia by hormone

treatment are unnecessary, ineffective and not without some possible hazards.

Gynecomastia developing in the adult male is usually seen in those of middle or late life, is almost invariably unilateral and is also due to functional endocrinologic disturbance, except for rare instances secondary to interstitial cell tumor of the testis, atrophy of the testis, hypophyseal adenoma or adrenocortical lesions. In later life, gynecomastia may be secondary to hepatic cirrhosis, with or without a history of alcoholism, in which instances the lesion presumably is due to the inability of the liver to accomplish intermediate metabolism of steroid hormones. Examination in the adult should include careful survey of the involved breast for a three-dimensional tumor, palpation of the testes and inquiry as to the possibility of cirrhosis of the liver. If a distinct, circumscribed, three-dimensional tumor is present, it should be excised to rule out carcinoma, although, in the male, fixation of the skin and pectoral fascia is almost invariably present when the diagnosis of carcinoma is first made. Otherwise, no treatment is indicated or useful, unless subcutaneous mastectomy becomes necessary for unsightly enlargement.

Dysplasias of the Female Breast ("Cystic Disease"). The dysplasias of the breast have achieved an unenviable distinction from the unnecessary complexity bestowed upon them in the past fifty or more years by contributors to the literature of surgery and pathology. A few years ago, a rough count of the nomenclature employed in several textbooks and a score or more of articles showed thirty-eight separate, frequently ambiguous, terms used to designate individual facets of the abnormalities of the hyperplasia-involution cycle in the breast, all of which are readily divisible into three principal phases. Some of the nomenclatural labels thus coined by fertile minds are polysyllabic and rather accurate, others are eponymic and misleading. Even the name of a symptom, mastodynia, has been conferred on a phase of this complex of dysplastic pathology. Some of these hair-splitting tags have come to mean different things to different people. An example is the eponymic designation of one situation as Schimmelbusch's disease, a popular term with clinicians probably for the suggestion of erudition implied in the use of so unusual a name, but which nowadays is seldom used to indicate the process described by Schimmelbusch.

The most reasonable hypothesis is that all of these dysplasias, no matter how disparate their gross and microscopic appearance may be after years of secondary changes, are nevertheless part of an over-all pattern. The highly variable patterns which develop can be correlated in terms of a single complex of abnormalities in epithelial and stromal components. Valid etiologic factors are endocrine dysfunction and atypical response in the mammary target tissue.

No satisfactory generic term is apparent, except the rather ambiguous expression employed here, dysplasias. The most inaccurate misnomer of all is "chronic cystic mastitis," for these changes are in no sense inflammatory. Cystic changes are frequently absent, and if present are more often minor than major, so that "chronic" is the only valid word in this traditional title. "Cystic" disease is a less offensive misnomer, for at least it disposes of the implication that the process is inflammatory, but quotation marks should be used around cystic for the reason indicated.

The division of the dysplasias into three general groups is accomplished naturally by considering the three dominant abnormalities in the hyperplasia-involution cycle.

Probably the earliest phase of dysplasia in most instances, and the persistently dominant phase in some women, is that of failure of involution, or persistent epithelial hyperplasia.

The reverse of failure of involution is hyperinvolution, the epithelium, rather than returning to the resting phase, undergoes progressive involutionary changes with flattening and blunting. With this, there is apt to develop a shedding off (mazoplasia) of the involuted epithelium and some secretory tendency. Cystic dilatations appear which at first are microcystic, as the process advances, probably by coalescence of small adjacent cysts, gross cysts of varying size may develop. The designation for this phase of hyperinvolution is its dominant manifestation, that of cystic development.

The stromal components of the breast are rarely unaffected by the epithelial changes of dysplasia. In the florid phase of proliferative activity, there is a concomitant though minor degree of fibroplasia, particularly in the periacinar and periductal layers and thus stromal reaction is also subject to either involution or hyperinvolution. When the latter change becomes dominant, progressive hyalinization of the connective tissue occurs, with eventual dense sclerosis. Generally, the

sclerosing changes occur in perilobular fashion, but the changes of advancing sclerosis may be extremely irregular. Foci of acinar hyperplasia or microcystic change may become circumscribed and compressed by sclerosing reaction. The same sort of sclerotic reaction may proceed within the walled-off area, isolating contained foci of epithelial elements which may be hyperplastic or cystic, or both. Such circumscribed areas may vary in size from microscopic foci to large areas, representing space-occupying tumors of several centimeters in diameter. In an advanced area of sclerosing reaction, formerly hyperplastic epithelium becomes compressed and pyknotic and these compressed, distorted, deeply-staining cells are the only residual evidence of the florid phase of hyperplasia of former years, now completely overcome by the violent intensity of the sclerotic stromal reaction. In this phase of dysplasia, as in the others, there may be a histiocytic response, less often some minor foci of lymphocytic infiltrate, probably responsible for the original designation of mastitis. These are the prominent changes in the sclerosing phase.

The least frequent phase of dysplasia is the secretory or exudative response, in which the secretory, acinar function is dominant. Whole lobules of mammary tissue become microcystic, the secretory products drain freely through the ductal system and appear at the nipple in the form of a pseudo-lactiferous exudate which is rarely profuse. This form of exudative dysplasia constitutes less than 2 per cent of all cases and may be regarded as a variant of the cystic phase.

It should be emphasized that pure examples of hyperplastic, cystic or sclerosing dysplasia are rarely seen. Some degree of all three phases generally will be found in long-standing cases of dysplasia. It is common for one phase to be dominant and it is the variegation of gross and microscopic appearance of acinar, ductal and stromal response which has given rise to the bewildering complexity of nomenclature. For example, dilatation of terminal tubules and acini with the formation of microcysts, usually diffuse, is the hallmark of so-called Schimmbusch's disease. With this, there is frequently an accompanying epithelial proliferation in the terminal ducts to form intra-ductal hyperplasia, and some degree of proliferative acinar hyperplasia which may spill into the adjacent stroma and resemble, superficially, an infiltrative process. These changes of ductal papillomatosis, adenosis

and microcystic formation are to be regarded only as various phases of hyperplasia and involution respectively. In some areas, ductal proliferation produces tubules with a blind ending, referred to as blunt-duct adenosis. The formation of gross cysts which are clinically palpable occurs in 15 to 20 per cent of women with dysplasia. In some instances a cyst, when exposed surgically, has a bluish color which promptly disappears when the cyst is incised or when the investing layer of tissue is removed. The coloration is simply an optical illusion through the surrounding fat and parenchyma but has acquired a special and unwarranted dignity by the designation of "blue-domed cyst." In 1 or 2 per cent of women with dysplasia, the sclerosing phase will become so overwhelming as to produce a hard, fixed tumor, occasionally with attachment of the skin, readily mistaken for carcinoma. Even on microscopic examination, especially of frozen sections, the extreme distortion and pyknosis of the formerly hyperplastic cells may mimic carcinoma. This lesion of *sclerosing adenosis*, or *adenomatosis*, has probably been the lesion most frequently misdiagnosed as carcinoma. It is most reasonably interpreted as an end phase of a severe sclerosing reaction in dysplasia.

Incidence. Clinically recognizable dysplasia of the breast is probably present in one-fourth to one-third of white women, based on the recognition of abnormal indurative changes. The process is practically always bilateral by objective criteria, although in some instances only one breast may be affected and occasionally but one segment of a breast. The process may appear immediately after puberty, but the great majority of dysplasias are seen in women beyond the age of thirty years and up to the climacteric. In the postmenopausal years, the process undergoes gradual resolution with rare exceptions. Pregnancy has a beneficial effect, particularly in the nulliparous woman. The disorder may improve remarkably after pregnancy or even fail to recur entirely.

Symptoms. The most frequent symptoms are soreness, tenderness or even severe pain beginning five to seven days premenstrually, and subsiding rapidly after the onset of menstruation. In some patients the period of distress is longer, beginning about the time of ovulation each month. Less often, the presenting complaint is the self-discovery of a lump in the breast with little or no soreness. It is very common for the

symptoms to occur in an irregularly periodic pattern, with months or even a year or more between periods of distress. In many women the severity of symptoms is profoundly influenced by emotional stress, such as domestic difficulties, or the death of a relative or friend from cancer of the breast.

Physical findings. When the dysplastic process is in its early phase, most often seen in younger women, the dominant change is most apt to be *hyperplastic*. The first evidence of such change is the appearance of small foci of abnormally granular or beady thickening, frequently with tenderness sharply localized to the area of altered tissue. In more diffuse forms, larger segments of the breast show granular, or beady, or almost vermiform indurative changes, often linear in arrangement. Not infrequently these changes vaguely resemble a string of beads of varying size. The hyperplastic phase of the process is that in which pain and soreness are apt to be most distressing.

More advanced changes are those in which some of the proliferative changes have evoked a sclerosing reaction of some degree and the larger lesions may now constitute three-dimensional tumors. Such indurative changes, however, can reach a size of even several centimeters in diameter and still be distinguishable as diffuse induration without the qualities of a space-occupying tumor.

When it is difficult to differentiate between advanced changes of dysplasia and a three-dimensional tumor in one or more areas, the physical findings may be related to the time of the menstrual cycle. Examination of questionable areas is best done a few days to one week after the onset of menstruation. Not infrequently, what seemed to be a three-dimensional lump during the premenstrual period will have decreased in size or disappeared entirely on re-examination after the onset of menstruation. For the woman who has the symptomatology and clinical findings of dysplasia, a good working rule is to re-examine "tumors" of 2 cm. diameters or less before proceeding with surgical approach for biopsy.

When the *cystic phase* of dysplasia is in the microcystic stage, the physical findings are indistinguishable from those of the hyperplastic or proliferative phase. If the cysts begin to acquire some gross size, even when less than 1 cm. in diameter, they are usually evident as smooth-surfaced moderately movable nodules without attachment to the adjacent breast. Their consistency

Figure 6 A, Exudative phase with discharge from nipple. Also indicated is the presence of palpable duct or ducts draining involved segment or segments of breast. No space-occupying tumor. B, Development of ductal papillomatosis in central third of breast.

depends on the amount of contained fluid. When gross cysts reach a size of several centimeters, they may be indistinguishable from solid tumors if the tension of the intracystic fluid is sufficient to distend the wall of the cyst. By this time, too, the surface may seem to be irregular because of overlying indurative change in the surrounding breast, although the largest cysts usually remain mobile and unattached to the skin.

In Figure 6 A is shown the exudative phase with discharge from the nipple. Also indicated is a not infrequent finding in such patients, the presence of a palpable duct or ducts draining the involved segment of the breast from which the pseudolacteal exudate originates. Lacking a space-occupying tumor, the only requirement in this situation is a smear of the nipple discharge to be examined only for red blood cells. If red blood cells are not found, the only indication is for periodic observation.

Figure 6 B illustrates the development of ductal papillomatosis in the central third of the breast, a ductal hyperplasia producing papillary excrescences of epithelium. Such areas of nodular, epithelial ductal hyperplasia are extraordinarily fragile and a considerable percentage of them give rise to minute amounts of serosanguineous discharge from the nipple. In this situation, one's first effort should be directed toward the search for a space-occupying tumor. If none is found, an effort should be made to locate the ductal area from which the bleeding is originating. If the origin of the bleeding

can be consistently demonstrated on two or more examinations, the involved ductal area should be explored as described below. Otherwise, if the patient is premenopausal, continued observation is justifiable, as only once in twenty times will bleeding from the nipple before the menopause indicate the presence of malignant change in ductal epithelium.

Relation of dysplasias of the breast to carcinoma. The relation of the dysplasias of the breast to carcinoma is still controversial, but the evidence for dysplasia as a precancerous process is flimsy indeed. If a patient with dysplasia has one breast predominantly affected, she has just as much chance of developing cancer in the less affected breast. Our experience includes over 600 women with objective criteria of dysplasia who were followed for periods of from two to twelve years. Only two of these patients developed carcinoma of the breast under observation, one had had an excess of mammary carcinoma in her family history. Various degrees of dysplasia are found in surgical specimens showing carcinoma, the frequency depending on the liberality with which the pathologist makes the diagnosis of dysplasia, but the only significance of such coexistence is that women with dysplasia may also develop carcinoma.

From our present state of knowledge, the following statements seem permissible in relation to this problem:

The microscopic lesion of blunt-duct adenosis may be a precursor to carcinoma.

The woman with objective changes of dysplasia deserves careful observation for the development of a dominant tumor which may be carcinoma. The development of such a space-occupying tumor, particularly if the dysplasia process is severe, may be masked by the chronic indurative changes. The intervals of observation should be four to six months.

For the woman with well-established dysplasia presenting multiple space-occupying lumps, good management is frequent observation and measurement of the tumors, particularly if the diagnosis has been established by prior excisional biopsy. Many of these lumps will disappear under observation.

Simple mastectomy is rarely, if ever, indicated for mammary dysplasia as a prophylactic procedure. From what has been said above, the only reasonable prophylaxis would be bilateral mastectomy, a therapeutic absurdity.

Treatment of mammary dysplasias. Three main problems are most pertinent:

The patient with symptoms and signs of dysplasia without a three-dimensional or dominant lump.

The patient with a space-occupying solitary tumor.

The patient with nipple discharge.

WHEN NO DOMINANT LUMP IS PRESENT. The patient without a dominant lump usually consults a physician because of soreness, tenderness or pain. For at least one half of such patients a careful examination, followed by adequate discussion and explanation of the process, is in itself adequate therapeutics. The reassurance of learning that the symptoms and the process are not related to cancer will satisfactorily diminish the severity of the symptoms. If the indurative changes are more than minimum, examination twice yearly should be recommended. In women with any degree of pendulousness of the breasts, adequate support should be recommended in the form of a fitted brassiere. During the period of greatest discomfort prior to menstruation, the majority of patients obtain great relief from wearing a brassiere at night, for which purpose a "sleeping" brassiere may be obtained if desired. Fitted brassieres should be so designed as to provide adequate uplift to the breasts and relaxation of the suspensory fascia.

These measures of reassurance and proper support of the breasts will produce satisfactory relief of symptoms in at least eight

or possibly nine of every ten patients. In the remainder, hormonal therapy is usually beneficial, either in the form of small doses of androgenic hormone in the first half of the cycle or progesterone in the latter half. If an androgen is employed, methyltestosterone by mouth is as effective as other preparations. It is desirable for the first two months to employ testosterone propionate by intramuscular injection, in dosage of 25 mg. two or three times weekly for two weeks, to measure adequately the response to treatment.

WHEN A DOMINANT LUMP IS PRESENT. When a dominant three-dimensional lump is present with physical findings characteristic of dysplasia elsewhere in the breasts, a very useful, preliminary, diagnostic measure is aspiration of the tumor as an office procedure under local anesthesia. The primary objective of this maneuver is to determine whether the tumor is solid or cystic. If it is cystic and can be evacuated completely, it will fail to refill in at least eight out of ten instances and thus the patient is spared the distress and expense of a surgical procedure for excision. In all such instances of successful aspiration of a cyst, the patient should be instructed to return in six weeks for re-examination. If the cyst has refilled, it is preferable to proceed with excision rather than to repeat the aspiration. Reaccumulation of fluid may indicate the presence of papillary changes in the epithelial lining. The development of carcinoma in a gross cyst developing in dysplasia is extremely unusual; not more than 0.5 per cent of all carcinomas of the breast give evidence of intracystic origin.

The procedure is simple and rapid. A site on the skin several centimeters from the tumor is selected, prepared with Zephiran solution, and an intracutaneous wheal is raised with injection of about 0.5 cc. of 1 per cent procaine solution. A small stab wound with a no. 11 scalpel is made through the wheal to permit passage through the skin of a no. 16 needle attached to a 20-cc metal-tipped syringe. With the tumor held stationary by one hand, the needle is advanced through the breast until it encounters the periphery of the tumor. The needle is then slowly pushed into the tumor. If the tumor is cystic, the needle usually passes suddenly into the cavity after the preliminary resistance of the fibrous wall. As thorough an aspiration as possible is done, the last of the fluid being obtained by combining further suction with some flat-hand pressure on the

tumor. A small dressing on the puncture wound can be removed in twenty-four hours. Our experience with cytologic study of the centrifuged sediment from such aspirations has been so unsatisfactory that it has been abandoned. The most reliable indication for further action in a successfully aspirated cyst is the reaccumulation of fluid.

If the solitary tumor proves to be solid rather than cystic, surgical exposure for biopsy is mandatory.

WHEN THERE IS DISCHARGE FROM THE NIPPLE. As indicated, if the patient with discharge from the nipple is found to have a space-occupying tumor, the nipple discharge should be disregarded except for cytologic study and prompt excision of the tumor for diagnosis recommended. For the patient with nipple discharge and without a three-dimensional lump, the next most important step is to determine whether or not the exudate contains red blood cells. If so, and the segment of the ductal system from which the bleeding originates has been located, the involved area should be exposed through a circumareolar incision with the patient under general anesthesia. Not infrequently, by careful palpation through the wound, nodular involvement of a duct by papillary change can be digitally determined. Prior to incision, it is possible in some instances to pass the blunt end of a straight skin needle into the orifice on the nipple through which the bleeding evades and to pass the needle gently into the duct. With or without such localization, a wedge-shaped resection of the involved part of the ductal system should be done, the radial extent of which should be one-third of the distance from the nipple to the periphery of the breast. If this excised portion of the ductal system fails to show a lesion and the patient is premenopausal, further action is not indicated, as the ductal papillomatosis coincident with dysplasia of the breast is not known to be a precancerous process. If the patient is postmenopausal, the likelihood of bleeding from the nipple being due to ductal carcinoma increases proportionately with each decade past the menopause. In this instance, if a preliminary, conservative ductal resection fails to demonstrate a benign papilloma, simple mastectomy should be done, particularly if the patient is ten or more years past the menopause. If the excised portion of the ductal system shows a fully developed malignant lesion, radical mastectomy is indicated.

Pseudoneoplastic Hyperplasia. There are

both ductal and acinar states of dysplasia which may resemble closely a genuine neoplastic process; there is no intent to lend to these lesions the dignity of separate entities. The fact is, however, that the histologic appearance of some of the more florid of these processes may be so atypical as to make interpretation difficult for the most experienced pathologists. This is to say that there are occasional situations where the differentiation between hyperplasia, with considerable atypism, and neoplasia is difficult indeed.

Reference has already been made to papillomatosis of the ducts and when there are focal areas of atypical nodular hyperplasia of ductal epithelium, the differentiation from genuine ductal papilloma may be extraordinarily difficult. Actually, the differentiation is largely academic, for there is no present evidence that either hyperplastic papillomatosis or the genuine papillomas are precancerous lesions.

Atypical acinar hyperplasia is most often seen where there are areas of long-standing cystic involution with development of papillary excrescences in the epithelial lining of such cysts, a condition referred to by some as papillary cystophorous hyperplasia. As in the ductal lesions, interpretations of such atypical changes are best deferred until permanent sections are available. The distinct criteria of malignant neoplastic change should be agreed upon by several pathologists before radical treatment is undertaken.

BENIGN NEOPLASMS

Fibroadenoma (Adenosfibroma). As indicated in Tables 1 and 2, this compound neoplasm of fibroblastic and epithelial origin exceeds all other benign neoplasms of the breast by a large margin. It is the only common mammary neoplasm in young women, with a peak of incidence between the ages of twenty and twenty-five. Fibroadenomas occasionally develop during adolescence, a few are seen in women from thirty years of age up to the age of the menopause and they are a curiosity in women in the postmenopausal years. Usually there are no subjective symptoms, occasionally, there may be slight tenderness. This neoplasm has highly characteristic physical criteria in its round or ovoid shape, smooth surface and most of all in its extreme mobility within the tissue of the breast. As indicated in Figure 7, the encapsulation of fibroadenomas is such

Table 2. Common Mammary Neoplasms

ORIGIN	BENIGN VARIANTS	APPROX. INCIDENCE (PER CENT)	MALIGNANT VARIANTS	APPROX. INCIDENCE (PER CENT)
I. Epithelium a. Ductal b. Acinar	Papilloma Adenoma	18 2	CARCINOMA Lobular Carcinoma	93.0 5.0

that gentle pressure over the tumor with a finger will cause easy displacement of the lump within the breast. Multiple fibroadenomas are seen in some 15 per cent of patients with this tumor. Approximately one in ten patients develops one or more additional fibroadenomas after the appearance of an initial tumor.

There is some reasonable evidence to support the thesis that fibroadenomas are related to hyperestrinism, for these neoplasms can be induced in animals by administration of estrogenic steroids and it is not uncommon to notice their rapid enlargement during pregnancy. Most of the malignant neoplasms known as cystosarcoma phyllodes have their origin in pre-existing fibroadenomas, which usually have been present for periods of five or more years.

Treatment is that of any undiagnosed three-dimensional tumor of the breast—surgical excision. Because of the characteristic physical findings and their predilection for occurrence in younger women, the accuracy of diagnosis for fibroadenomas is greater than for other space-occupying lesions of the breast.

Intraductal Papilloma. Genuine benign neoplastic growths in the form of papillomas of the ductal epithelium are a poor second in frequency. They occur in women of almost any age over twenty years. The majority, or about three of four, are located in

the ductal system of the central third of the breast; the remainder, more peripherally. Minute papillomas several millimeters in diameter may cause significant bleeding from the nipple. Larger papillomas often produce ductal obstruction which, if followed by bleeding into the obstructed portion, will result in severe distention with tenderness, pain and a palpable soft enlargement. Occasionally there will be periodic, rather profuse bloody discharge from the nipple as a duct alternately is obstructed and drains. Infection may complicate the picture, producing retraction of the nipple and secondary axillary lymphadeni-

Figure 7. Mobility of an encapsulated fibroadenoma.

tumor A small dressing on the puncture wound can be removed in twenty-four hours. Our experience with cytologic study of the centrifuged sediment from such aspirations has been so unsatisfactory that it has been abandoned. The most reliable indication for further action is a successfully aspirated cyst is the reaccumulation of fluid.

If the solitary tumor proves to be solid rather than cystic, surgical exposure for biopsy is mandatory.

WHEN THERE IS DISCHARGE FROM THE NIPPLE. As indicated, if the patient with discharge from the nipple is found to have a space-occupying tumor, the nipple discharge should be disregarded except for cytologic study and prompt excision of the tumor for diagnosis recommended. For the patient with nipple discharge and without a three-dimensional lump, the next most important step is to determine whether or not the exudate contains red blood cells. If so, and the segment of the ductal system from which the bleeding originates has been located, the involved area should be exposed through a circumareolar incision with the patient under general anesthesia. Not infrequently, by careful palpation through the wound, nodular involvement of a duct by papillary change can be digitally determined. Prior to incision, it is possible in some instances to pass the blunt end of a straight skin needle into the orifice on the nipple through which the bleeding exudes and to pass the needle gently into the duct. With or without such localization, a wedge-shaped resection of the involved part of the ductal system should be done, the radial extent of which should be one-third of the distance from the nipple to the periphery of the breast. If this excised portion of the ductal system fails to show a lesion and the patient is premenopausal, further action is not indicated, as the ductal papillomatosis coincident with dysplasia of the breast is not known to be a precancerous process. If the patient is postmenopausal, the likelihood of bleeding from the nipple being due to ductal carcinoma increases proportionately with each decade past the menopause. In this instance, if a preliminary, conservative ductal resection fails to demonstrate a benign papilloma, simple mastectomy should be done, particularly if the patient is ten or more years past the menopause. If the excised portion of the ductal system shows a fully developed malignant lesion, radical mastectomy is indicated.

Pseudoneoplastic Hyperplasia. There are

both ductal and acinar states of dysplasia which may resemble closely a genuine neoplastic process, there is no intent to lend to these lesions the dignity of separate entities. The fact is, however, that the histologic appearance of some of the more florid of these processes may be so atypical as to make interpretation difficult for the most experienced pathologists. This is to say that there are occasional situations where the differentiation between hyperplasia, with considerable atypism, and neoplasia is difficult indeed.

Reference has already been made to papillomatosis of the ducts and when there are focal areas of atypical nodular hyperplasia of ductal epithelium, the differentiation from genuine ductal papilloma may be extraordinarily difficult. Actually, the differentiation is largely academic, for there is no present evidence that either hyperplastic papillomatosis or the genuine papillomas are precancerous lesions.

Atypical acinar hyperplasia is most often seen where there are areas of long-standing cystic involution with development of papillary excrescences in the epithelial lining of such cysts, a condition referred to by some as papillary cystophorous hyperplasia. As in the ductal lesions, interpretations of such atypical changes are best deferred until permanent sections are available. The distinct criteria of malignant neoplastic change should be agreed upon by several pathologists before radical treatment is undertaken.

BENIGN NEOPLASMS

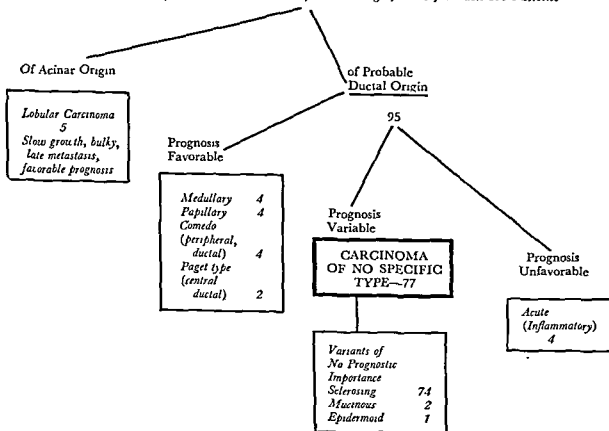

Fibroadenoma (Adenofibroma). As indicated in Tables 1 and 2, this compound neoplasm of fibroblastic and epithelial origin exceeds all other benign neoplasms of the breast by a large margin. It is the only common mammary neoplasm in young women, with a peak of incidence between the ages of twenty and twenty-five. Fibroadenomas occasionally develop during adolescence, a few are seen in women from thirty years of age up to the age of the menopause and they are a curiosity in women in the postmenopausal years. Usually there are no subjective symptoms, occasionally, there may be slight tenderness. This neoplasm has highly characteristic physical criteria in its round or ovoid shape, smooth surface and most of all in its extreme mobility within the tissue of the breast. As indicated in Figure 7, the encapsulation of fibroadenomas is such

specific type (Table 3). From the standpoint of gross pathologic changes, however, almost all of these common carcinomas provoke a sclerosing stromal reaction of variable intensity which is responsible for the hard, irregular consistency of almost eight of every ten carcinomas on clinical examination. When the sclerosing process is advanced, the neoplasm will exhibit a stony-hard consistency. This sclerosing reaction led to their separation in older classifications under the designation of *scirrhous carcinoma*, with the now discredited implication that intense sclerosis implied a more favorable prognosis. The informative value of the "scirrhous" reaction lies not in prognosis, but in gross diagnosis. It produces on cut section a retracted, gritty surface, with yellowish foci representing minute islands of fat which have become surrounded and isolated. There are two minor variants of this group, those with mucinous degeneration and those with epidermoid differentiation, representing approximately 2 per cent and 1 per cent respectively of all carcinomas.

There are four recognizable cell types of ductal carcinoma which, when predominant, may permit a favorable prognosis. These are, in order of descending importance from a

prognostic standpoint, medullary, papillary, comedo and Paget types of carcinoma. The *medullary carcinoma* is more apt to occur in women under the age of fifty. The tumors are frequently bulky in size and may appear to be encapsulated and often are mistaken grossly for fibroadenomas. Although they may appear to be highly malignant microscopically, their prognosis is five times more favorable than average because of their inherent tendency to remain localized to the breast and regional nodes for considerable periods. *Papillary cystadenocarcinoma* is an unusual neoplasm with a tendency to spread throughout the ductal system and to involve a considerable portion of the breast, often a quadrant or more. Inadequate excision of these neoplasms may be followed some years later by local recurrence without metastasis to regional nodes. The *comedo carcinoma* is an intraductal process in the beginning and may remain so limited for many months. Necrotic material is extruded into the lumina of the cancerous ducts and, on cut section, compression will cause extrusion of wormlike masses of necrotic tumor, consequently its nomenclatural prefix. Eventually, these neoplasms invariably invade mammary stroma and metastasize to regional nodes.

Table 3. Mammary Carcinoma—Variants of Clinical Significance for Each 100 Patients

tis, thus imitating a carcinoma of the central third of the breast

Treatment is the same as for dysplastic ductal papillomatosis. Radical management of this lesion is entirely unjustifiable, for the great majority are localized to a single quadrant and the process does not undergo malignant transition. This latter fact was well documented by a study of seventy-six patients with intraductal papilloma treated by local excision in whom follow-up for five to ten or more years showed no single instance of subsequent carcinoma.

Other Benign Tumors. Other benign neoplasms are so unusual as to occur in a total of not more than 1 per cent of all patients with lesions of the breast. Included are genuine intramammary lipomas (as compared to those developing in the subcutaneous layer of fat), adenomas and a few other esoteric items

MALIGNANT NEOPLASMS

Carcinoma of the Female Breast. Although there are some striking racial variations of incidence, carcinoma of the breast is the most common form of cancer in white women, amounting to about 22 per cent of all cancers. Uterine cancer ranks second, contributing about 19 per cent of total incidence. In women beyond the age of forty, the relative incidence of mammary carcinoma increases progressively with advancing age, when plotted against the size of the female population in each decade. Because of its natural history, with long duration of the disease in many women who do not obtain a curative result from treatment, the prevalence of this disease, or the yearly incidence plus the carry-over of previously diagnosed cases, far exceeds that of any other form of cancer in the female. A study of annual morbidity rates in upper New York state indicated five living patients with cancer of the breast for each death from the disease. The increase in mortality from carcinoma of the breast in the United States since 1920 has been progressive and the rate of increase considerably exceeds that of the total population. In 1920, there were 6665 recorded deaths in a population of 105,710,000; in 1948, the mortality was 18,928 in a population of 146,113,000. Currently, mortality exceeds 20,000 yearly. Nevertheless, the age-adjusted mortality is not as dismal as these figures would indicate and actually in some areas there is evidence of a slight decrease. In California, for example, the

age-adjusted mortality rate per 100,000 increased from 19.7 in 1910 to 28.0 in 1940, but in the decade from 1940 to 1950 decreased to 25.3.

Etiologic factors. The proximate cause of mammary carcinoma is unknown, but there are certain factors which are either almost requisite or appear in excess in the background of women developing this disease. A presumptive requisite is the exposure of the mammary epithelium to the long-continued stimulus provided by estrogenic and perhaps other steroids, for the development of carcinoma of the breast in women deprived of active ovarian function before the age of thirty is rare. Carcinoma of the breast also occurs in relative excess with the following historical features: family history of cancer of the breast, nulliparity, failure of the breast to perform its expected physiologic function (lactation) following full-term pregnancy, complications of lactation and late onset of the climacteric. It has been statistically demonstrated that carcinoma of the breast is more prevalent in women of better than average economic circumstances, but this may be related to a lesser degree of fertility. The evidence from a number of well-controlled studies in different countries lends adequate support to the belief that human mammary carcinoma is frequently a disease of genetic determination, although evidence is yet lacking that it is associated with a maternally transmitted, specific agent.

Speculation as to the possibility of administered estrogens acting as a causative factor is entirely unverified, although it is established that significant amounts of exogenous estrogen can produce augmentation of an existing, sometimes occult, carcinoma. For this reason, it is advisable to withhold the use of estrogens in women who have a family history of mammary carcinoma unless their use is considered essential. Women with a family history of mammary carcinoma deserve careful survey of the breasts at intervals of no less than six months. If the necessity for administration of estrogens arises, it is advisable to examine the breasts even more frequently during the first few months of medication.

Clinical-pathologic correlation. About ninety-five of each 100 mammary carcinomas are considered by consensus to be of ductal origin. Of this dominant group, nearly eighty are without distinctive morphologic features and may be designated as of no

rants, with only 5 per cent of lesions originating in the last-named area. Approximate figures are as indicated in Figure 8.

EVOLUTION OF LOCAL GROWTH. Evidence now available indicates that most, if not all, carcinomas of the breast have their inception as multicentric foci of microscopic neoplasia, whether of ductal or acinar origin. Most frequently, a single area of parenchyma is irreversibly involved and with progression of the process there is a confluence of the separate foci, usually with some stromal productive reaction, to produce a single gross tumor when the phase of clinical (palpable) recognition is reached. In a few instances, widely separated areas of parenchyma undergo simultaneous cancerization and formation of multiple gross tumors, most often observed in lesions developing during pregnancy or lactation. In about 1 per cent of all patients, bilateral carcinoma is present on first examination. In patients with only a single lesion demonstrable by gross examination, if scores of microscopic sections are examined from the remainder of the breast, other microscopic foci of carcinoma will occasionally be demonstrated (7 per cent). Further evidence of the biologic abnormality, which permits the genesis of mammary carcinoma, is the subsequent development of a second carcinoma in the remaining breast in 5 per cent of women surviving mastectomy for five or more years. In fact, the only mammary pathologic condition which appears with any frequency as a recognizable precursor of carcinoma is mammary carcinoma.

The interval of time between the inceptive phase of preinfiltrative neoplasia and its achieving such size as to be clinically palpable (1 cm. or even less in diameter) is

unknown, though it must be highly variable. It seems certain that, in at least a few patients, the preinvasive phase is of long duration. In the average lesion, available evidence indicates that from the phase of earliest infiltrative growth to that of a space-occupying tumor is at least six months, and more probably twelve or more months.

After reaching three-dimensional size, progressive extension into adjacent mammary tissue usually occurs and most often in irregular, pseudopodic fashion, producing a highly irregular surface and poorly demarcated edge. The rate of growth is not an exponential of time, periods of active local growth alternating with intervals of little or no increase in extent. With advance of the lesion, the skin becomes attached, infiltrated and eventually ulcerated, with subsequent secondary infection, necrosis and hemorrhage. Deep extension becomes attached to the pectoral fascia, which usually acts as a barrier to further direct spread, but extension through fascia and muscle may result in solid fixation to the thoracic cage. In the area of the axilla, the neoplasm may extend directly into and blockade the axillary space.

Notable variations from this average of local growth and extension are seen. In some fortunate patients, a dilatory, progressive ductal process will require several years to produce a palpable mass or to appear clinically as Paget's disease. In such women, dissemination of the disease beyond the breast is long delayed or may never occur. In lobular (acinar) carcinoma and in the more favorable variants of ductal carcinoma (medullary carcinoma, papillary cystadenocarcinoma and comedocarcinoma), the tendency is toward a walled-off or even pseudo-encapsulated tumor which may be bulky but is not actively infiltrating. Such neoplasms are expansile rather than infiltrative. Acute, or inflammatory, carcinoma represents a florid, overwhelming variant of infiltrative carcinoma, with multiplicity of origin, rapid extension and the circulatory congestive changes peculiar, in such degree, to this lesion.

A rare variant in local growth is one that may be of great diagnostic difficulty: the primary carcinoma of the breast which remains occult while disseminating widely. In some of these patients, the original lesion can be found only by serial sectioning of the breasts at autopsy. Less striking, but more frequent, are women whose first symptoms are those of either regional or distant metastasis in whom the primary lesion is so small in size

Figure 8 Distribution of carcinoma in various parts of the breast.

The term *Paget type* is employed here to designate those ductal carcinomas developing in the central third of the breast, in which the first manifestation of the disease may be the development of scaly indurative, erosive or actual ulcerative changes of the nipple and areola, the lesion first described by Paget. Such involvement of the areola is invariably a surface manifestation of an underlying ductal carcinoma, even though no tumor may be palpable. In some instances, the same type of ductal carcinoma may be present without involvement of the areola. This type of mammary carcinoma may remain limited to the central ductal area for varying periods before metastasis occurs.

The most ominous type of mammary carcinoma is that referred to as *acute or inflammatory carcinoma*. The lesion is a highly anaplastic variant with a rapid rate of growth and wide lymphatic embolization at an early stage of the process. Obstruction of the subdermal lymphatics by tumor emboli produces congestion with erythema and commonly some degree of lymphedema of the overlying skin. In some instances, no definable three-dimensional tumor is present, as the rapidly advancing neoplasm produces a diffuse, indurative change in the consistency of the affected portion of the breast. The only excuse for recognizing this as a separate form of mammary carcinoma is the ominous prognostic implication, for this is a surgically incurable form of the disease. Acute carcinoma is more often observed in premenopausal women and is particularly frequent in those carcinomas developing during pregnancy or lactation. It is largely for this reason that carcinoma of the breast in young women is believed by many to be of uniformly bad prognosis. The fact is that, excluding those carcinomas developing during pregnancy or lactation, the prognosis of mammary carcinoma in patients under the age of thirty is somewhat more favorable than for those of all other age groups combined.

Carcinoma of acinar origin. Approximately 5 per cent of mammary carcinoma exhibits histologic features consistent with an acinar origin and these lesions are designated as *lobular carcinoma*. Most often they are slowly growing neoplasms which usually have attained some considerable size when first seen. They have a distinct predilection for long-delayed metastasis to regional nodes. This neoplasm is seen more commonly in younger women than in those of the older age group. It typifies an occasional

situation where the clinical setting appears highly unfavorable by reason of a large primary lesion of long duration, yet it has a far better prognosis than the average, indifferent mammary carcinoma of small size and short duration. Experience has demonstrated that *in situ* lobular carcinoma should be treated by simple mastectomy rather than local excision.

Grading of mammary carcinoma. Apart from recognition of the 20 per cent or more lesions of special types described above, the pathologist cannot grade carcinoma of the breast with the prognostic accuracy he achieves in most carcinomas of squamous or epidermoid variety. The histologic inconsistencies are well illustrated by the medullary variant in which an "anaplastic" microscopic appearance is belied by a favorable natural history. The pathologist's recognition of these variants frequently is based on a combination of gross and microscopic features. For the remaining majority of carcinomas it is possible, by histologic criteria, to label a few as low grade in degree of malignancy, and another small group as having a high grade of malignancy because of striking anaplasia. These relative extremes of histologic architecture account for probably not more than 10 per cent or 12 per cent of the nonspecific carcinomas. Thus, a major fraction of some 65 per cent are processes which the pathologist can identify only as carcinoma, possibly using the word "ductal" to indicate probable epithelial cell-type. In these instances, information of more prognostic value can be secured from the pathologic extent of the disease and the combined facts of history and physical examination, all of which permit a limited evaluation of the biologic pre-determinism inherent in the host-neoplasm relationship for each individual patient. A further reflection on the limitations of microscopic grading is that, even in the few mammary carcinomas histologically separable as high or low grade in degree of malignancy, the subsequent course of the disease occasionally belies the histologic assumptions.

Patterns of local growth, regional and distant metastasis. A distinct excess of carcinoma is found in the upper outer quadrant of the breast, over 40 per cent originating in this quadrant. Next most frequent are the lesions of subareolar origin, accounting for over 20 per cent. In rapidly diminishing sequence of situational frequency are the upper inner, lower outer and lower inner quad-

planation for the areas of skeletal involvement is a spread through the paravertebral venous system. The same route probably accounts for cerebral metastasis, as it does for cerebral involvement in bronchogenic carcinoma and pulmonary abscess.

The variegations in patterns and timing of the appearance of metastasis are inexplicable. Activation of skeletal metastasis may occur thirty or more years following radical mastectomy. In some patients a solitary focus of metastasis will become evident, particularly in bone, one month or years after primary treatment, and will come under prompt control by palliative management, with a subsequent period of years of clinical quiescence ensuing. At the other extreme, innumerable sites of metastasis may erupt with explosive biologic force after apparently successful treatment, with lethal effect in months or even weeks.

Finally, there are not infrequent instances of spontaneous arrest and regression of metastatic mammary carcinoma, even when widespread. In some instances, the phenomenon is due to a "biologic adrenalectomy," or total replacement of the adrenal glands by metastasis. More often, spontaneous control is of short duration and due to inexplicable changes in host-tumor relationship.

Biologic predeterminism—the determinant of natural history. The traditional philosophy of surgeons and other clinicians in respect to the curability^o of cancer in general in past decades has been epitomized by an almost ritualistic slogan, "early" diagnosis and "early" treatment. "Early" has carried a dual implication—that if the elapsed time from first recognition of the primary neoplasm to initiation of treatment is short, the extent of the disease is more likely to be limited and the prognosis more favorable. The more extreme adherents of this form of clinical evangelism have reduced the natural history of cancer to a situation of enviable simplicity: the extent of a neoplasm is in direct ratio to the lapse of time since recognizable onset of symptoms or signs.

Actually, there are a few forms of cancer in which such a direct spatial-time relationship exists, but mammary carcinoma is one of a number of major human cancers which provides convincing refutation of such clinical

pragmatism. As indicated previously, there are rare instances in which a primary carcinoma of the breast never becomes of such size as to be clinically discoverable, while the occult focus disseminates widely with lethal effect. In such an extreme instance, as far as the original source of disease is concerned, there is zero-delay on the day of death, in terms of ritualistic adherence to "early" diagnosis. Or, the patient's initial symptom may be pain due to skeletal metastasis from a carcinoma of the breast so insignificant in size as to escape any but the most meticulous examination.

At the other extreme of the biologic scale are the mammary carcinomas so dilatory in growth, so late in development of metastatic potential, that simple mastectomy within three years of recognition of a local abnormality usually could achieve a cure, if one could recognize clinically such biologic sluggishness of growth. About 20 per cent of all carcinomas of the breast make up this group of biologic sluggards of neoplasia. Reference to Table 3 will indicate that a substantial portion of the slow-growing neoplasms are pathologically recognizable as processes of more favorable prognosis. While the variants so indicated in Table 3 add up conveniently to 19 per cent, it is proper to recognize that not all of these neoplasms actually pursue a more favorable course. Also, some of the genuinely slow-growing carcinomas are of nonspecific type, and no clinical or pathologic criteria are available to characterize these less ominous, neoplastic mavericks.

Mammary carcinoma provides the most variegated pattern of human cancer of any major organ site. Relative accuracy in evaluation of "early diagnosis" of the disease can be secured only by determining the total extent of involvement in terms of time (duration) and local space-occupation (size of primary lesion).

Of these two factors, duration is least reliable, for obvious reasons common to most historical data. With an adequate sample, however, such data have some validity. The more objective factor is provided by actual measurement of the primary neoplasm in a series of surgical specimens provided by radical mastectomy. Both of these factors of "earliness" are most readily tested by correlation with the presence or absence of axillary nodal metastasis in the same surgical specimens, for this is the important single prognostic criterion in operable lesions.

When the axillary nodes are without evi-

as to be detectable only by careful examination.

Secondary changes within mammary carcinoma are most dependent on rapidity of growth and size and are proportional to both. They include areas of hemorrhage, zones of necrosis and secondary infection.

In a few patients, satellite cutaneous nodules develop from subdermal lymphatic tumor emboli, an ominous sign.

REGIONAL METASTASIS. Axillary lymph-nodal metastasis has been of predominant interest for two reasons, one anatomic and the other clinical. With the largest group of carcinomas originating in the upper outer quadrant, initial regional metastasis most frequently occurs through the axillary (principal) pathway to the axillary and retropectoral nodes. Carcinomas primary in the lower outer quadrant have a similar predilection for axillary spread. Even the lesions primary in the medial hemisphere may take the axillary route of earliest dissemination, those in the upper inner quadrant are as apt to take the axillary as the internal mammary pathway, while those of the lower inner quadrant more often spread by the latter route. The primary neoplasms of subareolar origin are unpredictable and may, as seems logical, spread through the subareolar lymphatic plexus.

From a surgical standpoint, the standard procedure of radical mastectomy produces only the axillary group of lymph nodes for histologic study. The presence or absence of demonstrable involvement of axillary nodes determines the final (pathologic) staging of the operable case and also offers criteria of considerable value in prognosis.

Current investigative studies of the value of internal mammary node dissection, in addition to conventional mastectomy, have focused interest on the frequency of metastasis in these superficially located, intrathoracic nodes. Of those carcinomas originating in the medial quadrants and operable, over 50 per cent have set up such deposits, while about 20 per cent of those in the lateral quadrants have so disseminated.

The subclavicular nodes are least commonly involved of all the regional nodes and such spread is usually concomitant with supraclavicular nodal deposits.

It should be emphasized that both the supraclavicular and other cervical nodes, as well as the internal mammary chain, are not regional, but distant nodes in the true sense, both by anatomic and biologic considerations.

The mechanism of lymphatic spread is usually by embolization, seldom by permeation.

DISTANT METASTASIS. For those instances in which a sequential sort of spread is the pattern, axillary nodal involvement is followed by supraclavicular deposits, then by mediastinal nodal metastasis. Or, through the internal mammary pathway, direct spread to the pleura and perhaps lymphangitic pulmonary involvement represent an anatomic sequence.

The vagaries of remote dissemination are such that any orderly, progressive sort of spread is seldom demonstrable. From a practical, clinical standpoint, *it is essential to remember that any spread beyond the true, regional nodes is almost invariably an indication of generalized disease.* Thus, metastasis in a single supraclavicular node, histologically proved, is as ominous as spread to other, more distant sites. It seems equally certain that occupation of a single node in the internal mammary chain is of similar dire import. The dissection of such nodes will probably produce no increase in curability and little in the way of palliation.

Of greatest importance to the clinician is a knowledge of the most frequent sites of distant metastasis, so that an intelligent search may be made both in presumably operable, primary cases and in the follow-up of postoperative patients. From combined information provided by clinical and autopsy studies, distant sites may be listed in the following order of descending frequency:

- Mediastinal nodes, lung and pleura
- Bone
- Liver, peritoneum
- Adrenal
- Brain
- Ovaries

It is also helpful to have in mind the sites of predilection of skeletal metastases, which by order of diminishing frequency, are:

- Ribs
- Lumbar spine, pelvis and upper femora
- Dorsal, cervical spine
- Skull

- Upper humeri and scapulae

Skeletal metastasis from carcinoma of the breast is predominantly osteolytic, although some osteoblastic reaction is common at the advancing periphery of bony lesions. Occasionally, osteoblastic metastasis is seen, though rarely is it as sclerosingly eburnated as that common to deposits of prostatic carcinoma.

It is of interest that the only rational ex-

less secure basis, one may speculate that the determining factors governing neoplastic aggressiveness or host-resistance may reach back to the genetic inheritance of the host. This is to say, that the behavior of a neoplasm is determined by genetic factors.

From the clinical standpoint it seems obvious that the growth pattern is established long before the symptomatic stage is reached and thus for practical purposes is predetermined. The growth potential of the neoplasm, arrayed against whatever defensive reactions are evoked in the host, eventuates in a biologic complex which determines the natural history of the disease. For the clinician, this constitutes biologic predeterminism.

From all of this, it is apparent that biologic factors, more than the time of treatment, the size of the neoplasm or even the type of treatment, most profoundly influence prognosis. This does not mean, however, that reasonably prompt, effective treatment is without importance to the woman with carcinoma of the breast, both for curative and palliative purposes.

Indicated in Table 5 is an estimated distribution of 100 patients based on factors inherent in biologic predeterminism. Twenty individuals would have a favorable result, usually curative in effect, even with something short of ideal treatment, at any time

up to three years after onset. About fifty-five of each 100 have neoplasms of high growth potential and inadequate host-resistance, in whom regional or distant metastasis is established before the primary lesion is clinically apparent. In the remaining twenty-five, there is the relationship between time, space-occupation and metastasis implied in the traditional concept of "early" diagnosis. For these twenty-five women, the extent of their disease is indeed a function of time. It is for this group that not only prompt, but adequate, effective treatment may mean the difference between cure and failure, between life and an early death.

These concepts of mammary carcinoma lead to the following conclusions:

Only in some twenty-five of each 100 patients will "early" treatment, by detection of a small tumor of short (known) duration, contribute to curability.

In seventy-five of each 100 patients, curability is established by natural history (biologic predeterminism), not by factors of duration or local spatial extent. Twenty of such patients are readily curable, fifty-five are incurable, and for biologic reasons in both instances.

Clinical evaluation of curability, which is to say, operability, should not be influenced by duration or the size and extent of the primary neoplasm. Some lesions of long

Table 4. Mammary Carcinoma—Incidence of Stages I and II by Known Duration of Primary Tumor

DURATION (MONTHS)	STAGE I (PER CENT)	STAGE II (PER CENT)
1 month or less	55	45
>1-6 months	35	65
>6-12 months	48	62
>12 months	22	78

dence of metastasis by histologic examination of all discoverable nodes, the neoplasm is, from the standpoint of the surgical specimen, limited to the breast and designated as stage I P (pathologic as compared to clinical staging). If axillary nodal metastasis is proved histologically, the process is stage II P.

The relative incidence of stages I P and II P is related to the known duration of the tumor in Table 4, based on data from several sources. It is obvious that lesions of very short duration (thirty days or less) have a distinctly better prognosis than do long-neglected tumors, the relative incidence of favorable (stage I P) cases being 55 per cent and 22 per cent respectively. However, after a delay of one month, there is no significant change in the incidence of axillary extension between the remainder of the first six-month period and the next full period of six months.

For successive increments in size of the primary carcinoma, as shown in Figure 9, a comparable situation is demonstrated. With carcinoma of the breast just within the range of palpability (1 cm. diameter or less), the prognosis is most favorable, but even in such very "early" neoplasms, over 50 per cent have already seeded into one or more axillary nodes. The obverse of this biologic coin of chance again reveals that fraction of less ominous growths, when the primary tumor has achieved the impressive dimensions of more than 5 cm. diameter, 23 per cent of such patients are yet without regional (axillary) nodal metastasis. The progress in spatial extent from more than 1 to 3 cm., and on to 5 cm., is a period of growth during which no change in incidence of regional metastasis is evident.

One reason for this seeming paradox is that the more rapidly growing, more ominous neoplasms tend to provide the patient with

Figure 9 Relation of size of primary carcinoma of breast to involvement of axillary nodes by microscopic examination (stage I P, nodes negative; stage II P, nodes involved).

more disturbing evidence of local or regional abnormality than do the less aggressive tumors. Such striking signs as rapid local growth, erythema or edema of the skin or a large node in the axilla bring most women with unfavorable lesions to treatment in the first few weeks or months after onset. More of the group with slowly progressive tumors, procrastinate and after many months of delay may still present evidence of local disease only. Thus, the "early" cases of short duration include a disproportionate number of unfavorable cancers, obscuring the true value of "early" treatment for some patients.

The natural history of untreated carcinoma of the breast now becomes easy to comprehend when considered in the light of the foregoing information. From several sources, the percentage of patients surviving without treatment are, in round figures, as follows:

YEARS	PER CENT
1	75
3	40
5	20
10	5

Here, again, the figure of 20 per cent survival at five years is most impressive, pointing once more to that fraction of dilatory neoplasms of low growth potential and little or even no capacity for metastasis.

The sum of this evidence constitutes in-evitable proof of a host-neoplasm relationship by which a balance of power is established between the invaded and the invader. The biologic factors involved in this struggle for survival are unknown, but the evidence also indicates that the struggle is decided in the preclinical phase of the disease and probably during its earliest inception. On a

involvement, and evidence of low growth potential.

- B. *More extensive axillary, and especially apical, nodal involvement.* Axillary nodes, bulky or adherent to each other or to the skin.

Lymphedema or erythema of the mammary skin, including "inflammatory" carcinoma.

Other evidence of a pattern of rapid growth.

III. All other cases. Regionally remote or distant metastasis

This group includes patients with:

- Fixation of the breast to the chest wall
- Metastasis to supraclavicular nodes
- Contralateral axillary metastasis
- Those with distant metastasis

Clinical staging of lesions in operable cases is only a working evaluation of the disease in respect to axillary metastasis. The histologic determination is the final diagnosis. Where differentiation of the two is necessary, a capitalized C or P is used, for Clinical or Pathologic Staging.

The inaccuracy of clinical evaluation by competent individuals is apparent in numerous reports, of which the following data are representative. For each 100 women with carcinoma of the breast undergoing radical mastectomy, clinical impression concerning axillary nodal disease will be in error to the extent indicated below.

The clinical error is greater in the direction of inability to detect lymphadenopathy found by gross or microscopic examination. In brief, the experienced clinician's "false negative" evaluation of axillary nodes is 40 per cent, while his "false positive" error is only 15 per cent. The usual cause of a "false positive" conclusion is the presence of large nodes secondary to inflammatory reaction.

In a few centers, effort toward securing

more accurate information on the extent of the disease is pursued by obtaining lymph nodes for biopsy from the scalene and internal mammary areas, prior to radical mastectomy. If such nodes are found to contain metastasis, palliative treatment is employed.

Initial clinical investigation. The patient with a tumor of the breast which may be carcinoma deserves careful preliminary study, the extent of which will be indicated by symptoms and physical signs. The reaction of many physicians toward an undiagnosed lump in the breast is as emergent as that of a fireman toward a blaze in a gasoline refinery. From what has been said above concerning its natural history, it is obvious that carcinoma of the breast does not metastasize overnight or, for that matter, in a fortnight. The "fire engine" approach to the undiagnosed lump in the breast is more apt than not to be a disservice to the patient, both in respect to proper management and the patient's psychologic reaction.

The following information, all of which is relevant to phases previously described in detail, should be secured:

1. Known duration of tumor
2. Observation of change in size, over what interval
3. Observation of redness of skin, change in size of breast
4. Change in appearance of nipple or discharge therefrom
5. If premenopausal, whether the breast is sore or lumpy premenstrually and the present phase of the cycle
6. Fertility, lactation and abnormalities thereof
7. Previous operations for mammary or pelvic pathologic conditions
8. Family history of mammary carcinoma
9. Inquiry concerning symptoms which might indicate metastatic involvement in common sites:

a. Persistent cough, or dyspnea (mediastinal, pulmonary)

b. Pleuritic type of pain (pleura, ribs)

c. Pain of recent origin or altered character, particularly if persistent, which may be referred to sites of bony metastasis (ribs, spine, pelvis)

d. Headache, vertigo or visual disturbance (brain)

In addition to meticulous survey of the breasts and regional areas, general examina-

duration with extensive local lesions are curable.

Effort should be made, in each patient, to evaluate the biology of the lesion in terms of historical (approximate rate of growth) and physical (local, regional and distant) indications of curability or incurability.

If it were possible to provide the most effective treatment now possible for all patients with a minimum period of delay (one month or less), the maximum theoretical curability would be 45 per cent.

Stages of disease. Staging is the effort to express the extent of the disease and is of vital importance for it determines both treatment and prognosis. There are two approaches to staging, clinical and pathologic.

I. Clinical stages Every primary (untreated) tumor of the breast which may be carcinoma and apparently operable should be regarded by the clinician preoperatively as cancer and such survey methods as may be indicated are employed for evidence of possible metastasis. Clinical staging is highly inaccurate even in the most competent of hands.

2. Pathologic stages The pathologist's effort in determining spread of disease is more accurate than the clinician's but usually is limited to a study of the operative specimen from operable cases. Most often, of course, the specimen is the product of radical mastectomy, from which the most important prognostic information secured is the presence or absence of axillary nodal metastasis. Not less than fifteen and up to thirty or more axillary nodes should be found by careful search, without clearing of the specimen, after an adequate axillary dissection. The prognostic value of the findings can be increased considerably if the surgeon tags the axillary apical portion of the specimen during the dissection. The axillary contents then become divisible into three approximate areas.

Level I—Below the tendon of the pectoralis minor

Level II—Posterior to this structure

Level III—Apical area, above the pectoralis minor

The prognosis becomes progressively worse with the demonstration of nodal metastasis from level I to level III.

Occasionally, histologic study is necessary to determine spread of disease beyond the area of conventional radical mastectomy, most frequently through excisional biopsy of suspected supraclavicular nodes, contralateral axillary nodes or skin nodules.

The most valuable and most logical clinical classification of any cancer, when its mode of dissemination permits, is that which expresses three possible stages of advance of the disease:

I. Limited to primary site

II. Regional nodal involvement apparently present

III. Distant metastatic foci are demonstrated beyond reasonable doubt

In some situations, as in carcinoma of the breast, some subdivision of regional spread to indicate degree of such extent is useful and practical. For clinical usefulness, adherence to the basic concept of three stages seems of obvious value, although some classifications of more complex design, such as Portmann's, are perhaps more accurate and are widely employed.

The deficiency of any clinical staging is that it represents only the demonstrable extent and location of disease at the moment of evaluation. It gives no hint of the kinetic phase or the growth potential of the neoplasm. For example, two patients may exhibit primary tumors of the same size, and comparable degrees of axillary lymphadenopathy, yet in one there will be historical information indicating no change in size or extent in six months, while in the other the mammary tumor has doubled in size in three months and the nodes have developed in a matter of weeks. If the history of the latter patient is underscored by objective findings of edema or erythema, one is confronted with an entirely different neoplasm, biologically considered, than in the other patient, even though the spatial occupation by neoplasm is nearly identical.

Incorporated in the following outline of clinical staging are some considerations of biologic variability in stage II. This outline has been used for some years at the Los Angeles County Hospital.

Clinical stages

I *Disease limited to the breast*

May include patients with minimum changes in the skin (early retraction) without actual cutaneous infiltration.

II *Primary lesion of breast with clinical evidence of metastasis to axillary nodes, or more than minimum involvement of skin, or both*

A *Axillary nodes are discrete. No axillary lymphadenopathy.*

Cutaneous involvement with or without ulceration, but concomitant with definite axillary nodal

diagnostic measure, prior to palliative radiotherapy or chemotherapy.

Its success is entirely conditioned on the interest and cooperation of the pathologist. This implies either an interest in cytology or attention to detail in the fixation and subsequent processing of the slivers of tissue submitted, in contrast to routine procedure for larger blocks of tissue.

CLINICAL LABORATORY PROCEDURES. Unfortunately, there is as yet no specific test for any type of cancer. Nor do any of the current efforts in refinement of nonspecific serologic reactions offer sufficient promise of relative accuracy for routine clinical use.

The *sedimentation rate*, in the absence of concomitant and particularly inflammatory disease, is of some value as it is usually elevated in mammary carcinoma if the primary lesion is bulky or if there is more than minimum axillary nodal spread. Remote metastasis is almost invariably accompanied by highly abnormal rates.

While not as valuable an indication of skeletal metastasis as is acid phosphatase in prostatic carcinoma, the alkaline form of this enzyme is present in concentrations above the average range in some six out of ten women with bony metastasis. When a patient with a known carcinoma of the breast has symptoms consistent with such metastasis, consistently elevated levels of *serum alkaline phosphatase* on two or more determinations are almost confirmatory of skeletal or hepatic metastasis, regardless of roentgenographic findings in respect to bone detail.

The woman who faces the possibility of an operative procedure for carcinoma of the breast requires both physical and psychological evaluation.

Physical evaluation. Only severe concomitant disease or extreme senility and deterioration should interfere with the choice of surgical treatment. In women with cardiovascular disease, adequate medical work-up is indicated, but rarely should it constitute a contraindication to radical mastectomy. Careful medical management before, during and after operation is, of course, mandatory. The same attitude should hold for patients with diabetes or other major medical problems.

Age, as in any other major surgical venture, is more a matter of biology than chronology. Some women of sixty-five are more senescent than others a decade or two older. The mere fact that a woman has survived

past the biblical three score and ten is usually evidence of a biologic fortitude which will carry her safely through a radical mastectomy, no matter how frail she may appear. We have had an experience of two patients past ninety years of age, both of whom had a smooth convalescence following a hurried but radical mastectomy, one of them surviving four years to die of coronary thrombosis without clinical evidence of recurrence.

Psychologic evaluation. To many women the prospective mutilating effect of mastectomy seems far more drastic and much more difficult to accept than the most extensive sort of intra-abdominal operation. To such women the breasts are more closely identified with physical integrity than are any other structures save those of the head and neck. Such an attitude is not peculiar to younger women or to those whose physical attributes would command admiration.

In any woman there will be, with rare exceptions, more than a little reluctance to face the situation. Curiously enough, the problem is apt to be less difficult when the patient has had prior, though unrelated, major operations.

For his own protection the surgeon must inform the woman with an undiagnosed tumor of the breast that a mastectomy may be required, no matter how remote the possibility may seem. However, in most patients it seems desirable to create the impression that the necessity of a radical operation is unlikely, even in the presence of almost certain clinical signs to the contrary, an unverified clinical diagnosis of cancer is psychically damaging to the patient and hazardous for the clinician.

When the diagnosis of cancer is established, the frankness with which the situation is discussed, or the evasions which are sometimes almost mandatory, must depend on the clinician's attempt to evaluate the emotional status of each patient, with help from the family when available. The clinician's effort in psychotherapy, amateurish though it may be, is as integral a part of management as the technical details of definitive treatment. Large doses of optimism, warranted or not, are salutary adjuvants to physical theapensis.

Methods of Treatment. Since the early years of this century, radical mastectomy, as originally described by Willy Meyer and Halsted, has been the definitive therapeutic measure for operable carcinoma of the breast. In the past twenty years, a growing

tion occasionally shows signs of possible importance in relation to metastatic sites.

Hepatomegaly

Ascites

Neurologic, such as Horner's syndrome due to pressure on the cervical sympathetic chain by enlarged, deep cervical nodes, or signs of cranial neuropathy from cerebral metastasis

Ovarian mass

Abnormal signs in examination of the chest with advanced intrathoracic disease are relatively unimportant, as the roentgenogram of the chest is far more accurate

RADIOGRAPHIC STUDIES The absolute pre-operative requirement in every patient with an undiagnosed tumor of the breast is roentgenograms of the chest, preferably anterior stereoscopic and lateral views. Some clinical authors emphasize routine skeletal surveys, but the yield of positive findings is so low in primary, asymptomatic cases as to be entirely out of proportion to the burden imposed on the radiologic laboratory and the cost involved. If the tumor is of questionable operability, a simple form of bone survey should be done. This may consist of a large (14- × 17-inch) anteroposterior film of the lumbosacral spine and pelvis and a similar large film taken laterally. Providing the previously mentioned roentgenograms of the chest have been made with adequate penetration, the ribs and thoracic spine are reasonably visible. If the patient has symptoms which may be due to skeletal metastasis, additional appropriate studies should be ordered

It should be remembered that the radiographic method is a study in shadows and considerable destruction of bone may be present without evidence of radiographic abnormality, even with technical work of high quality and expert interpretation. It has been estimated, by study at autopsy, that two-thirds of the diameter of a vertebral body in the exposed plane is usually destroyed before the metastatic focus becomes apparent on the roentgenogram. Clinical evaluation of pain is thus of great importance, persistent, localized pain of increasing intensity, with the added evidence of elevated serum alkaline phosphatase, may be as significant as a questionable area in a roentgenogram.

NEEDLE BIOPSY. The theoretical dangers of needle biopsy are entirely speculative and several reports concerning long-term follow-up of many patients with cancer of the

breast subjected to the procedure fail to indicate any adverse influence.

The value of needle biopsy is limited to those instances in which the material secured is diagnosable as cancer, either by histologic or cytologic techniques. *Negative findings are valueless.* When carcinoma is determined by needle biopsy, the procedure obviates the necessity of a preliminary biopsy and rapid frozen section in the operating room, reducing the duration of anesthesia and operation by fifteen to thirty minutes.

For almost fifteen years the resident staff in Surgery and Radiology of the Tumor Surgery and Radiation Therapy Services of the Los Angeles County Hospital has employed needle biopsy as a routine measure in tumors of the breast clinically consistent with carcinoma. The relative simplicity of the technique is evident from the fact that after a month or so of experience, performing several needle biopsies weekly, the residents usually obtain samples as satisfactory as those secured by more experienced individuals.

Needle biopsy may be done by one of two methods

Aspiration of the tumor by a large-caliber needle and cytologic study of smears from the aspirated material.

Securing a core of tissue from the tumor by one of several special needle-type devices, of which the most commonly used is the Silverman needle. The core of tissue is placed in fixative and processed by histologic technique

Of the two methods, the histologic method is preferred by most pathologists.

Our considerable experience, as indicated above, permits these conclusions concerning needle biopsy:

Successful use of the technique requires reasonably frequent practice. He who "tries" a needle biopsy several times in a year is likely to have a low opinion of the procedure. Unless one can use needle biopsy weekly rather than monthly, it is better to rely on open, surgical biopsy.

In tumors subsequently established as carcinoma, needle biopsy should produce a positive report seven out of ten times.

It is preferable to limit the technique to tumors clinically suspect and 2 cm. or more in diameter

It is of greatest value in confirming a diagnosis of carcinoma, for the record, in patients with inoperable disease and without superficial lesions suitable for conventional biopsy. It is, therefore, a highly appropriate

If the biologic concepts enunciated are valid, by which supraclavicular node involvement is as ominous as more distant metastasis, such surgical heroism may be only of palliative, certainly not of curative, value.

Extreme pessimism has been the keynote of recent writings of some biometricians, who maintain that no difference in survival statistics is reflected following any method of treatment. Such conclusions are iconoclastic both by the statistical methods employed and the failure to differentiate between survival of long duration with and without disease.

All of these viewpoints are inspired by a growing recognition of the inadequacy of presently available treatment for mammary carcinoma. Nevertheless, until more effective, physiologic or chemotherapeutic methods become available, conventional radical mastectomy remains the definitive measure for operable, possibly curable, cases. The clinician's primary responsibility, then, is to separate *operable* from *inoperable* cases. Inoperability may be established either on technical or biologic considerations, an effort which is attended only by relative success.

Referring now to the clinical classification of mammary carcinoma previously outlined, stages I and III present no problem. Stage I, without clinical evidence of spread beyond the breast, requires immediate radical mastectomy. Stage III, with extension beyond the homolateral axilla, is eligible for palliative treatment.

The varying degrees of local growth and axillary nodal involvement constituting stage II may tax the judgment of the most experienced clinician. Combining considerations of physical findings and attempts to assess the rate of growth, the classification employed here divides stage II lesions into two categories:

Ia. Eligible for immediate radical mastectomy

Ib. Categorically inoperable

The primary problem in stage IIb cases is to filter out some lesions which, though clinically unfavorable especially in relation to the extent of the primary lesion, may nevertheless secure a better palliative, and even an occasional curative, result by radical mastectomy.

This filtering process can be accomplished with a fair degree of accuracy by employing irradiation as a therapeutic test. In general, radiosensitivity indicates biologic incurability and, conversely, radioresistance may mean a more favorable prognosis in a clin-

ically extensive process. At least, failure of a stage IIb lesion to regress with a moderate dosage of irradiation will indicate that better palliation will be secured by operative measures, either simple or radical mastectomy.

In practice, the therapeutic test of radiosensitivity in stage IIb cases may be employed as follows. The primary lesion is treated through two opposing portals, the axillary nodal disease through a single direct field. Daily treatments are given to a total of 1500 r to 2000 r tumor dose to the primary (breast) lesion and 1000 r to the axilla, in a period of fourteen to eighteen days. At the end of this trial period, the primary, radiosensitive carcinoma should show a 40 per cent or more regression by measurement, with similar reduction in the size of axillary nodes. This degree of radiosensitivity indicates genuine incurability, as well as the probability of satisfactory local and regional palliative control by irradiation; a full course of roentgenotherapy is then employed. Failure to respond to the therapeutic test usually is an indication of a less ominous growth pattern and radical mastectomy may be undertaken with suitable additional postoperative irradiation depending upon microscopic findings in the removed axillary nodes.

Histologic confirmation of the diagnosis of carcinoma should precede any therapeutic test of radiosensitivity, even though the clinical evidence seems unmistakable. Stage IIb cases, owing to the extent of the disease, usually present areas of involvement permitting biopsy under local anesthesia if the clinician does not employ needle biopsy.

Surgical biopsy. The surgical approach to undiagnosed tumors of the breast, whether clinically suspected of cancer or not, should be made with the patient under general anesthesia by a surgeon who is competent in radical mastectomy, with the stage set for the latter procedure if it is indicated. The key figure in this setting is the pathologist, who must be skilled in the preparation and interpretation of frozen sections. An experienced surgical pathologist can make an exact frozen-section diagnosis in a high percentage of breast lesions, but such accuracy is a product of training, experience and, above all, interest in assuming this responsible role. Failing these requirements, either because of disinterest or absence of a full-time pathologist in smaller hospitals, it is best to do excisional biopsies and await the preparation of paraffin sections. If the surgeon has had adequate training

recognition of unfavorable biologic factors, such as outlined by Haagensen and Stout, has emphasized a group of patients technically operable but categorically inoperable. Still more recently, the therapeutic pendulum has swung in two opposite directions. One philosophy, represented by the work of McWhirter and his associates at Edinburgh, favors operative treatment by simple mastectomy, followed by intensive roentgenotherapy to the regional lymph-nodal areas. The end results after five and ten years reported by McWhirter are equal to those after radical mastectomy, but two practical objections to his procedure are apparent:

The level of dosage (3700 r tumor dose in three weeks) employed by McWhirter is far more intensive than that customarily employed by American radiologists. In actual practice, only a small minority of radiologists in the United States whose major or exclusive interest is in radiotherapy will be willing to employ the intensive treatment and meticulous planning which are required if the results reported by McWhirter are to be achieved.

External irradiation of this intensity, regardless of the quality of the beam, results in some sequelae in a fair percentage of patients, the hazard of which becomes greater with survival beyond five years after treatment. Although the incidence and severity of pulmonary fibrosis are considerably less than were predicted, and although radiation osteitis usually is not of significant importance, the telangiectasia and atrophy of the skin are a source of distress in some women in whom such changes become advanced.

The main disadvantage of the McWhirter technique is the fact that every woman with carcinoma of the breast is subjected to the same intensive radiotherapy, regardless of the absence or presence of involvement of axillary lymph nodes, which cannot be determined in the absence of axillary dissection. As has been described above, at least 20 per cent of patients, even with the lesions of largest local size and longest duration, still have no evidence of spread to the regional, axillary nodes. When the primary tumor is small (in the range from 1 to 1.5 cm.), 50 per cent or more of patients are without axillary spread. Thus, the uniform application of radiation therapy without actual knowledge of the presence of regional metastasis is an unnecessary exercise for somewhere between twenty-five and fifty of each 100 women.* It is equally ob-

vious that the routine use of radiotherapy is of no value in those patients in whom spread is by humoral rather than by lymphatic channels. The McWhirter technique also employs routine irradiation of the chest wall in the customary operative area of a radical mastectomy. Inasmuch as only 5 per cent to 15 per cent of women in most series of cases exhibit chest wall recurrence, this also indicates an unnecessary amount of irradiation for about eighty-five of each 100 patients. Most clinicians who employ post-operative x-ray therapy following radical mastectomy prefer that the chest wall not be irradiated so that in the event of local recurrence there will have been no impairment of skin tolerance for local irradiation.

Assuming that crude five-year survival following radical mastectomy with intelligent use of postoperative irradiation is equal to that reported for simple mastectomy and routine irradiation, radical mastectomy remains the preferable procedure in view of the preceding considerations. Two recent reports concerning significant numbers of patients do indicate that the standard radical mastectomy produces results equal to, or superior to, those reported from Edinburgh. In 1957, Watson reported on 629 patients treated in Saskatchewan from 1944 to 1949 and, although smaller in number than the group reported by McWhirter, it is nevertheless a comparable experience, as it represents over 85 per cent of all the breast cancers in this Canadian province. The five-year crude survival was 48.3 per cent with radical mastectomy and almost routine use of postoperative irradiation, compared to 42 per cent for the Edinburgh series. In 1958, a report of 8396 proved cases, for 1935 to 1953 in Connecticut (Ryan et al.), showed an improvement in five-year survival from 46.3 per cent for the first seven-year period to 51.0 per cent. There was a significant difference favoring the survival of patients treated by radical surgery over those treated by limited surgery.

The reverse of this approach is the super-radicalism currently employed by some surgeons in the United States, in which the standard procedure of radical mastectomy is extended to include one or more of the following:

- Homolateral neck dissection
- Dissection of the internal mammary chain of nodes
- Contralateral mastectomy

* The same may be said of axillary dissection, but one obtains thereby important prognostic information, as well as guidance for proper treatment.

Various incisions may be employed in radical mastectomy, depending on the location of the primary lesion. When feasible, variants of the transverse (Stewart) or arrowhead (Greenough) incisions are more acceptable from a cosmetic standpoint than the Meyer-Halsted type.

Irrigation of the operative area before closure with a solution of some chemotherapeutic agent has been employed to an increasing extent since 1957, although conclusive evidence of its value is not yet established. Various alkylating agents have been employed, but the substance which seems most promising for this purpose is Cloropactin (monoxylchlorosene).

Closure of the wound must be done without undue tension on the thin skin flaps. Split-thickness skin grafts may be required, but in the majority of patients a more satisfactory closure is obtained by using the adjacent skin. This is accomplished by sliding flaps, usually from lateral and lower costal areas.

POSTOPERATIVE CARE. Postoperative care is concerned mainly with two important objectives: wound healing and function of the arm. Although the primary contribution to healing is wound closure with minimum tension, a departure from the customary occlusive type of pressure dressing has produced a distinct increase in primary healing. A no. 28 Robinson (hard rubber) catheter, with four or five additional openings cut into the distal 6 cm. of the tube, is inserted through a stab wound below the axilla in the posterior axillary line for dependent drainage. The tube is fixed to the skin with a single suture, which should also make the stab wound airtight. Negative suction through the tube is started in the recovery room or even in the operating room if there has been more than an average amount of generalized bleeding. Negative suction is applied, preferably through a power-operated source such as the Pratt-Chaffin unit, maintaining a constant pressure of about -118 mm. of mercury, although the usual two-bottle Wangenstein suction can be substituted. This achieves early fixation and revascularization of skin flaps with far greater effectiveness than is accomplished by pressure dressings. Suction is maintained for three to five days or until the amount of exudate recovered in the trap bottle is less than 100 cc. in 24 hours. On the second postoperative day, the patient is taught to disconnect the Robinson catheter from the tube to the suction machine so that she

can have increasing periods of ambulation and no restriction in bathroom privileges.

Negative suction is employed and no dressing of any sort is used, as it has been demonstrated that complete exposure of the wound provides a combination of drying, cooling and electrolyte and protein environment which is most hostile to bacterial growth. Assuming that there has been meticulous edge-to-edge closure, the wound becomes sealed in less than two hours. During this time, a nonsterile bath towel may be placed over the wound to absorb the early exudate. In the recent experience of one group, this combination of negative suction and exposure of the wound has produced better than 80 per cent primary healing in over 100 radical mastectomies. Antibiotics have not been employed and there is no conclusive evidence of their value as a routine postoperative measure.

Active motion of the arm should begin on the day of operation. The most valuable single exercise in prompt recovery of function of the arm is brushing the hair. The patient should have a hairbrush within reach constantly and be encouraged to spend much of her time using it. She should aim at being able to make the full sweep of the brushing motion on the opposite side of the head in five to seven days after the operation. More varied exercises are of value later.

Ambulation should begin on the evening of operation and increase daily.

CHEMOTHERAPY SUPPLEMENTARY TO RADICAL MASTECTOMY. Cole and his associates have provided convincing evidence that in animal experiments free-floating cancer cells can be destroyed by chemotherapeutic agents given intravenously or intraperitoneally. The early results of controlled human tests, in which randomly matched postoperative patients who have or have not received such chemotherapy are compared, appear promising. It is still too early to evaluate the results.

Radiation therapy supplementary to radical mastectomy. This is a therapeutic issue with contradictory statistical evidence concerning its value. The issue is clouded by the reports of some surgeons who, with a lamentable lack of objectivity, order radiation therapy only for patients with stage II P cases with extensive axillary disease. Such bias results in comparing unfavorable with favorable series of cases, rather than measuring the effectiveness of irradiation in all stage II P cases. The techniques of post-

Figure 10 Incisions for exploration and biopsy. 1, Curved areolar for lesions in the central third 2 and 3, Curved peripheral incisions 4, Inframammary incision for deeply located tumors

pathology, he will be able to make a diagnosis on the physical features of the cut surface of at least seven of every ten carcinomas. Whether he proceeds with a radical mastectomy without histologic confirmation is his own responsibility, for there will be rare instances in which the most typical gross findings are not verified by histologic findings.

Incisions for tumors in different areas of the breast are indicated in Figure 10. Radial incisions should be avoided, for they are more prone to keloidal reaction and stretching than any other and are frequently sensitive, even painful. For exploration of the central third of the breast, including the ductal area, the curved areolar incision permits wide exposure by reflection of skin flaps and the resultant scar is almost invisible after a few months in most patients. An inframammary incision, to expose the under-surface of the gland for a deeply located tumor, is disadvantageous if a radical mastectomy is indicated.

For tumors with the physical criteria of a benign process, or of small size (in order of 1 cm. in diameter), *excisional biopsy* is preferable. In all instances, a margin of adjacent, apparently uninvolved tissue should be removed with the lesion, even though it may seem encapsulated. In tumors clinically suspect of carcinoma, *incisional biopsy* has theoretical advantages, fewer lymphatic radicles are divided and there is a lesser hazard of cancer cells being spread in the wound or on gloves or instruments.

TECHNIQUE OF INCISIONAL BIOPSY After preparation and draping of the area required for radical mastectomy, the surgeon does a secondary draping to leave exposed only the site of incision. An adjacent drape is spread, on which the instruments em-

ployed are placed, to be discarded if cancer is present. Incision is made through the skin and directly down to the surface of the tumor. Retractors are placed to expose the lesion adequately and, with a scalpel, a wedge of the tumor is excised. If the gross appearance suggests carcinoma, the site of biopsy may be electrocauterized, hemostasis completed and the skin closed tightly while awaiting the frozen section report. If the tumor is not carcinoma, skin flaps are reflected and the entire lesion excised with a margin of adjacent tissue.

If carcinoma is confirmed, tight closure of the skin is followed by electrocoagulation of the line of incision. Biopsy instruments are discarded, as are the drapes around the incisional area and any wash basins used; gloves are changed and the entire operative area is repainted with antiseptic.

If rapid frozen-section diagnosis is not available, at least one study has indicated that there is little, if any, influence on prognosis by first excising the tumor and performing radical mastectomy for carcinoma two or more days later. With either approach, the most important consideration is meticulous attention to the "aseptic" sort of technique outlined above, for cancer cells can be implanted, even in donor sites while grafting skin. Some postoperative local recurrences are probably due to a similar mechanism.

Radical mastectomy. This procedure requires a precise knowledge of anatomy and meticulous adherence to operative detail. Competence in the procedure is acquired only by training and experience. Cardinal requirements include:

1. Wide reflection of thin skin flaps in the area of the primary lesion

2. Reflection of skin flaps beyond the mid-line anteriorly, to the posterior axillary line posteriorly, to the clavicle above and the upper area of the rectus sheath below

3. Sacrifice of both pectoral muscles, major and minor

4. Meticulous axillary dissection, including the sheath of the axillary vein. If multiple enlarged nodes are found around the axillary vein, its resection will permit a more thorough dissection than is otherwise possible. Resection of the axillary vein entails no increased hazard of postoperative edema of the arm, provided x-ray therapy is not employed.

* Some studies indicate that five-year survival increases in proportion to the number of lymph nodes found in the surgical specimen.

sions are those with recurrent or metastatic disease following definitive treatment who also require palliative care. As almost one-half of operable patients develop recurrence or metastasis within five years after radical mastectomy, it is obvious that palliative management is the clinician's major problem.

At present, palliative treatment depends on control of the disease by irradiation and therapeutic alterations in steroid metabolism, with surgical procedures for removal of local or regional disease occupying a minor but sometimes useful position. In general, the best palliation will be secured by conservation of the therapeutic ammunition, reserving the larger-caliber and more drastic bullets until the less spectacular shots have outlived their usefulness. Thus, many women respond well to roentgenotherapy of successive areas of metastatic involvement over a period of years, before the disease becomes so disseminated as to indicate the need for hormonal therapy.

With this philosophy in mind, the following outline of the management of inoperable mammary carcinoma was recently developed by the Subcommittee on Breast and Genital Cancer, Committee on Research, American Medical Association

A. Palliative Radiotherapy

With one exception, inoperable breast carcinoma, whether primary or recurrent and/or metastatic postoperative, should have preliminary palliative treatment by radiotherapy if the dominant lesions are encompassable by this modality. The exception is that of metastatic lesions (not local recurrence) of soft tissue in women five years or more postmenopausal. For these patients, primary palliative treatment by estrogens is preferable. The postmenopausal phase is defined as that following the last menstrual period, or what may reasonably be accepted as such.

Even in this situation, however, moderate doses of irradiation will produce more rapid regression than if estrogens alone are employed. It should be noted that "soft tissues" is employed to designate such sites as lymph nodes, contralateral breast, chest wall or subcutaneous areas in any part of the body and does not include visceral metastasis. When employed concurrently with the initiation of hormone therapy, a tumor dose of 1000 rads to not more than 1500 rads seems to be entirely adequate.

All major areas of skeletal involvement with significant weight-bearing function should have the benefit of x-radiation, regardless of other management. Large tumor doses are not necessary for control of most metastatic lesions in bone. Tumor dosage in the range of 1500 rads will be adequate in most instances and, in some patients, will permit re-treatment of the same area at a later time without concern over skin tolerance.

B. Alterations of Steroid Metabolism

I. Indications for Artificial Menopause

Induction of menopause should precede the use of androgenic hormone in premenopausal patients. In the absence of medical contraindications, oophorectomy seems preferable. Roentgen-induced menopause is a satisfactory substitute in women from 40 to 60 years of age, provided that a dosage of 500 to 1200 r is delivered to the midpelvis in a minimum period of ten days to two weeks. In younger women, proportionately larger dosage is necessary. About one-third of the patients will exhibit early objective regression of disease after artificially induced menopause. Androgens should not be used in these responsive subjects until clinical evidence of active disease is again apparent.

II. Hormones

The hormone of choice is related entirely to the patient's physiologic age in reference to the menopause. Up to, and for a period of three years after the menopause, whether natural or by artificial induction, the initial steroid of choice is androgenic; following this arbitrary period, estrogens are consistently superior to androgens at all postmenopausal ages and in any and all sites of metastasis.

C. Initial Trial of Treatment

Any attempt to alter steroid metabolism should be pursued for a minimum period of three months before objective criteria of effectiveness are evaluated. During this time, observation at intervals of one to three weeks is essential, with careful inquiry as to symptomatic response and development of side effects. Objective changes in breast cancer occur slowly with altered steroid metabolism and may not be apparent until later than three months. Therefore, if the disease remains static, treatment should be continued. If objective evidence of unaltered progression of the disease is apparent during the trial period, the method of treatment

operative irradiation employed also influence its possible effectiveness. With these reservations as a guide in evaluation of reported results, it seems evident that postoperative roentgenotherapy in stage II P carcinomas increases five-year survival with clinical control by 10 per cent.

In a study of 8396 proved cases in Connecticut from 1935 to 1953, the one group of patients showing a significant improvement rate of 87 per cent in later years were those having irradiation after radical surgery. The improvement in patients in stage II was significant at the 5 per cent level.

Preoperative x-ray therapy in operable cases (stage IIa C) is not of value in the opinion of most American surgeons and radiologists, although of value as a therapeutic test of radiosensitivity in more advanced (stage IIb C) cases, as outlined earlier in this section.

There is no reasonable basis for postoperative roentgenotherapy of patients with stage I P lesions, with two possible exceptions. If evidence indicates that an inadequate axillary dissection has been done, the limited number of nodes removed may constitute inadequate evidence that the process is actually stage I P. For lesions located in the medial quadrants, irradiation to the mediastinal area is a logical sequel to operation, even though all axillary nodes are clear. In most instances, postoperative roentgenotherapy is best directed toward regional lymphodal areas (axillary, supraclavicular and mediastinal). Irradiation of the chest wall in the operative area is inadvisable, either the dosage given is so small as to be of no value or, if adequate, is hazardous in respect to the poorly vascularized skin and the frequency of pulmonary fibrosis. Should local chest-wall recurrence develop later, its control by focal irradiation is frequently most effective but is not possible if the tolerance of the skin has been lost by prior irradiation of large portals, even in small dosage.

If postoperative radiotherapy is to be employed, its intent should be for its possible cancericidal, not psychologic, effect. This implies the desirability of its direction and planning by one whose interest in radiation therapy is more than casual. It also requires conditioning of the patient to a course of treatment given daily for several weeks with the subsequent acute, though transient, cutaneous reaction over the treated areas. Intensive irradiation can sterilize mammary carcinoma; when employed as primary treat-

ment in operable cases, the original focus is destroyed in about one-third of the subjects. According to recent reports, a cancericidal effect in lymphodal deposits may be obtained with a similar frequency. Thus, although only 5 to 7 per cent of recurrences are axillary in origin, the effectiveness of radiotherapy supplementary to surgery is somewhat greater than this figure, but only after adequate treatment uniformly employed for all patients with axillary nodal involvement.

Treatment of pregnant or lactating patient. Carcinoma of the breast developing during pregnancy or lactation is usually attended by symptoms and signs indicating an unfavorable biologic pattern, such as rapid growth, bulky primary lesion, cutaneous erythema or extensive axillary nodal involvement. So common is this pattern that the patient with carcinoma of the breast which becomes manifest during pregnancy or lactation came to be regarded as categorically inoperable and incurable. More recently, a number of reports have proved the error of this assumption, with figures as favorable as 30 per cent five-year survival. The same criteria for separation of operable and inoperable cases should be employed as for any carcinoma of the breast, with the expectation that about two-thirds of these patients will present inoperable, incurable disease, best treated by palliative irradiation. For patients developing mammary carcinoma during pregnancy, the following outline seems to be a satisfactory guide.

At any stage of pregnancy the carcinoma should be treated as though the patient were not pregnant. Thus, if radical mastectomy is indicated, the procedure is done with little danger of abortion or premature delivery.

If the fetus has not reached the stage of viability, therapeutic abortion should be recommended, the decision being left to the patient and her husband. If the pregnancy is five months or more in duration, little if any benefit will accrue from its interruption.

Palliative treatment. Over 40 per cent of all patients with mammary carcinoma are incurable at the time of initial examination. In some institutions for the medically indigent, the proportion is considerably higher. The basic reason for incurability of most primary, untreated lesions, however, is the unfavorable biologic characteristics of the disease in this fraction of patients. Added to the patients with inoperable, primary le-

is necessary before clear-cut and conclusive indications can be established for their use.*

End Results. As in any form of cancer, valid measurements of effectiveness of treatment require observance of certain criteria, some of which are:

1. The total experience (absolute survival rate) of the institution or individual must be reported, thus avoiding the factor of selection.

2. The sample must be of significant size and homogeneity.

3. Successful follow-up of patients should exceed 90 per cent and untraced patients should be counted as failures.

4. Differentiation must be made between "survival" and "survival without disease," as determined by clinical examination.

5. Survival after treatment should be compared with survival of untreated patients. Therapeutic success is represented by the extent to which survival of treated patients exceeds that of untreated or by the percentage of survivors without clinical evidence of disease at various intervals.

6. A method of presenting survival in terms of yearly "survivorship function" is more enlightening from a biometric view, as developed by Berkson and Gage. The logarithm of survivals is plotted as ordinate against time as abscissa to produce a curve giving the death rate for any given year. The same curve for a normal population of similar age may be shown also for contrast.

Results of "curative" treatment. A further consideration in mammary carcinoma is its variability and tendency to late recurrences and appearance of metastasis. The arbitrary yardstick of five years following treatment is thus of limited significance; end results in terms of clinical control at the end of ten years are of significant value.

End results in operable cases following definitive treatment, in terms of survival

without clinically evident disease, are of value provided total experience is reported and grouping of operable cases is clearly defined. Most of the apparent improvement in end results reported in recent years by some surgical centers is the result of selection, stemming from recognition of criteria of inoperability.

In respect to *total experience*, an approximation of the best results of treatment recently reported from various centers, compared with the natural history of the disease, is as follows:

	SURVIVAL	
	5 YEARS (PER CENT)	10 YEARS (PER CENT)
Untreated	20	5
All patients treated, including those with recurrent disease	30	15
All patients, primary treatment	40	25

For considerations of prognosis, end results as related to the stage of the disease are important. The usual distribution of pathologic stages reported by most authors is:

	PER CENT
Stage I	30
Stage II a	25
Stage II b	30
Stage III	15

In other classifications (such as Portmann's) stages II, III and IV are equivalent to II a, II b and III above.

Representative results of definitive, primary treatment are:

	SURVIVAL	
	5 YEARS (PER CENT)	10 YEARS (PER CENT)
Untreated	20	5
Stage I	75	60
Stage II a	40	25
Stage II b	20	10
Stage III	0	0

In stage II cases, the extent of axillary lymphodal involvement by histologic examination is a determinant of survival. If the axilla is divided into three levels in relation to the pectoralis minor muscle, five-year results bear the following relation to ascending metastatic involvement:

AXILLARY NODAL METASTASIS	SURVIVAL—5 YEARS (PER CENT)
Level I only (lower third)	65
Level II (mid-axilla)	45
Level III (apical nodes)	20

alectomized patients Removal of the hypophysis can be accomplished surgically with a reasonable mortality rate. Surgical removal is a more satisfactory procedure than attempts to destroy the hypophysis by the implantation of a radioactive substance such as yttrium⁹⁰. Section of the hypophyseal stalk is not a satisfactory substitute for hypophysectomy. A series of patients is now under study in whom the hypophysis is removed before the development of metas-

Figure 11 A, Photomicrograph of biopsy tissue from a primary, inoperable carcinoma of breast before treatment B, Photomicrograph of biopsy tissue from same neoplasm after steroid (estrogenic) hormone therapy with major regression Note diffuse fibrosis and cellular changes.

should be changed. Increase in pain during the first two weeks of treatment is not uncommon and is not an indication for change of treatment. Later in the course, pain may be significant indication of progression.

D. Plans of Treatment with Steroid Agents

The standards of reference for treatment are:

1. Androgen—testosterone propionate in oil in dosage of 50 mg three times weekly by intramuscular injection
2. Estrogen—oral diethylstilbestrol, 15 mg. daily, usually in three divided doses. In the rare patient who cannot tolerate oral medication, injectable material may be substituted

If objective response is achieved, these dosage schedules may be maintained until reactivation of disease is apparent, some patients do well on lesser, maintenance doses. The Committee has no data indicating any superiority in tumor-suppressing effect by any steroids over that obtainable with testosterone propionate and diethylstilbestrol (Fig 11).

E. Secondary Plans of Therapy

For the patients not responding to initial therapy, or those escaping control after initial regression, the following sequence of further management is advised:

1. Discontinue hormone therapy for one month, as some patients will then exhibit regression and should have no further treatment until reactivation of disease is evident.
2. Patients nonresponsive to androgen who have not had bilateral oophorectomy should now be so managed. If

oophorectomy has been done, experience has shown that a cautious trial of estrogen is indicated.

3. Postmenopausal patients with disease not controlled by estrogens may have a trial of testosterone, given in the same manner as already described.

F. Hazards

Emphasis should be placed upon the most dangerous side effects of steroids: fluid retention in the early phase of treatment and hypercalcemia. Both of these complications are the most frequent in patients with cardiovascular-renal disease, which in elderly patients may become apparent only after the initiation of steroid therapy. Such concomitant disease makes these complications more ominous and demands more frequent observations.

G. Experimental Procedures

Both adrenalectomy and hypophysectomy are in an experimental phase of development and should not be employed generally. It seems evident that almost one-half of women showing evidence of a steroid-dependent neoplasm, as indicated by prior response to administered steroids or oophorectomy, will secure a further interval of control of their disease following adrenalectomy.

Some investigators have published results indicating that hypophysectomy as a primary palliative measure is more effective than adrenalectomy with or without oophorectomy. There is, as yet, insufficient evidence to establish a significant difference between the two procedures in control of the disease or longevity. Further experience with larger groups of patients

dissemination. Axillary nodal metastasis is usually evident and pulmonary metastasis may also be demonstrated at the initial examination.

If axillary or other metastasis is not evident, radical mastectomy is indicated. More commonly, with axillary extension already obvious, the disease is incurable and the most effective management is castration, reserving stilbestrol for later use when the disease escapes the customary postorchietomy period of control.

Survival for five years is less than 10 per cent.

Sarcoma. Sarcomas constitute about 1 per cent of malignant neoplasms. The most frequent connective tissue neoplasm is the *cystosarcoma phyllodes*, generally accepted as arising in a pre-existing fibroadenoma. As is consistent with such an origin, this tumor is actually of compound structure, although the epithelial component is, with rare exceptions, largely overwhelmed by the fibroblastic process. There is divided opinion on the nature of the neoplasm; some authors maintain that *cystosarcoma phyllodes*, in defiance of its ancient nomenclature, occurs in benign and malignant variants, while others state that if a sufficient number of areas are histologically examined genuine sarcoma is invariably found. In rare instances, both epithelial and fibroblastic elements contribute to the structure of a compound, malignant neoplasm. The tumor is characteristically bulky, nodular and expansile, of slow growth but capable of attaining an impressive size in cases of long duration, giving rise to the term "giant fibroadenoma." Encapsulation is the rule. Metastasis is infrequent and then usually by hematogenous rather than lymphatic routes, with the lungs the most frequent site of deposit. It would seem best to employ the term *adenofibrosarcoma* for this dilatory neoplasm. For the more bulky variants, simple mastectomy is adequate treatment. When relatively limited in extent, wide resection of the breast is a proper procedure. Axillary dissection is not indicated.

Specific types of sarcoma occur in the breast, but their total number is considerably less than the *adenofibrosarcomas*. Included are mesenchymoma, even true teratoma, liposarcoma, hemangioperithelioma and sarcoma exhibiting metaplasia to simulate chondrosarcoma and osteosarcoma. The treatment of these rare neoplasms is surgical, of such scope as may be indicated by the extent of the individual lesion. Lym-

phatic dissemination is so unusual as to preclude concomitant axillary dissection. Prognosis is highly variable but is usually related to the degree of differentiation or anaplasia exhibited by the neoplasm.

All of the foregoing figures are, of course, approximations of currently reported, statistically valid results. Some individual authors, for example, have reported five-year clinical control in stage I cases as high as 90 per cent, but such results usually reflect either a small sample or factors of selection.

Representative of those performing combined radical mastectomy and mediastinal node dissection, J A Urban reports as follows on his first seventy-five cases in a personal communication

	TOTAL NO	5-YEAR SURVIVAL
All nodes clear	29	25
Axillary nodes only invaded	19	14
Internal mammary nodes only invaded	3	1
Both axillary and internal mammary nodes invaded	24	10
Entire group	75	50

If these patients had had a standard radical mastectomy, the study of axillary nodes only would have divided them as follows, with five-year survivals

Stage I — $29 + 3 = 32$
 5-year survival = 26, or 81 2%
 Stage II — $19 + 24 = 43$
 5-year survival = 24, or 55 8%

These figures for five-year survival exceed those commonly reported, but individual reports of larger series treated by radical mastectomy are not significantly different, e g, Haagensen's results of 86.2 per cent in 160 stage I cases and 50.5 per cent in 196 stage II cases. The over-all five-year survival is identical for Urban and Haagensen, or 66.6 per cent. In view of the fact that, at least by microscopic findings, the mediastinal dissection was unproductive in forty-eight of Urban's seventy-five patients, a more impressive increase in survivals at the ten-year level seems required to justify the combined procedure.

Local recurrence of carcinoma, i e, in the operative area, is variously reported at 6 per cent to over 20 per cent, the usual figure ranging from 10 per cent to 14 per cent. The more rigid criteria of operability produce lower rates of local recurrence and the adequacy of the operative procedure is also an important factor.

Results of palliative treatment. Occasional patients experience long-term control of recurrent and advanced metastatic disease with irradiation and steroid therapy, but over-all results have to be measured in terms

of months rather than years. The most important result of palliative treatment is the relief of symptoms and rehabilitation, even when longevity is not significantly increased. Relief of pain from skeletal metastasis occurs in 70 per cent or more of patients both with irradiation and steroids, though less than half of such patients show objective evidence of healing. Long-term control by steroid therapy is most frequent in soft-tissue peripherally-located metastasis in postmenopausal women treated with estrogens. In some of these patients the disease is inactivated for two or more years.

The final report of the American Medical Association Subcommittee on Breast and Genital Cancer is an analysis of 945 women with disseminated mammary carcinoma, of whom 581 were treated by androgens and 364 by estrogens as the only form of palliative therapy. Follow-up was successful in 86.5 per cent (818). The following summary of the Subcommittee's report should be a guide to the proper choice of hormonal therapy, most notably in its rejection of the notion that androgens are superior to estrogens for skeletal metastasis.

Androgens produced objective regression in 21 per cent of premenopausal patients, and in from 13 to 28 per cent of postmenopausal women. Estrogens, limited properly to postmenopausal patients, induced regression in 16 to 40 per cent of patients. Both types of hormones were more effective after the eighth postmenopausal year, at which time both reached a plateau of performance, but with the estrogens inducing a higher relative frequency of regressions (40 per cent) than the androgens (27 per cent).

In cases with unsystemic dissemination, estrogens produced a greater degree of control in soft tissues at all postmenopausal ages, and were equal, or superior, to androgens for skeletal and visceral metastasis.

Responsive patients had significantly longer survival after both androgenic and estrogenic therapy, while the unresponsive individuals in all groupings had identical, average survivals characteristic of untreated patients.

Steroid sex hormones are sufficiently effective in postmenopausal women to deserve a primary trial in the treatment of disseminated mammary carcinoma. After the fourth postmenopausal year estrogenic substances are the agents of choice.

Carcinoma of the Male Breast. Less than 1 per cent of all mammary carcinoma is of the male breast. The pathologic condition and natural history are the equivalent of the disease in the female. Unfortunately, the lesion is usually relatively advanced and clinically obvious when first seen, probably because of the rudimentary structure of the thin mammary plate with early lymphatic

THE MEDIASTINUM

By JOHN M. DORSEY, M.D.

JOHN MICHAEL DORSEY, the son of a doctor in a small community in central Illinois, attended the University of Chicago and Rush Medical College. Trained in surgery at the Mayo Clinic, his attention has become focused upon the surgical problems best solved by a combined, expert knowledge of the abdominal and thoracic cavities. A Professor of Surgery at Northwestern University, he is Chairman of the Department of Surgery at Evanston Hospital.

The mediastinum is a potential space enclosed within the parietal investing layers of the right and left pleural spaces laterally, the sternum in front, the vertebral column behind and the diaphragm inferiorly. The thoracic mediastinum becomes the cervical mediastinum above the level of the thoracic inlet. The mediastinum is important surgically because within it are located the heart, giant vessels, trachea and the tissues of its bifurcation, the esophagus, important nerve trunks, the thoracic duct and the thymus gland.

It is convenient to divide the mediastinum into anterior and posterior divisions. The anterior division is further divided into superior and inferior compartments, the middle mediastinum can be best considered as part of the posterior division. Figure 1 diagrammatically illustrates these divisions in the sagittal view.

It is obvious that the heart and pericardium are the principal occupants of the inferior division of the anterior mediastinum. The structures about the tracheal bifurcation are likewise the essential occupants of the midmediastinum, whereas the aorta, esophagus, thoracic duct and important nerve trunks obviously lie in the posterior compartment.

The pressure within the thoracic mediastinum is less than atmospheric. It is important to the normal physiologic function of the mediastinal structures that this be relatively undisturbed. Trauma with extravasation of the fluid contents of one of the mediastinal structures (i.e., air, blood, lymph, inflammatory exudate, gastroenteric fluid), new growths, congenital deformities and disturbances in pulmonary function, as by atelectasis or pneumothorax, may alter this normal pressure directly or by displacement of structures so as to seriously threaten life.

MEDIASTINAL EMPHYSEMA

The escape of air into the mediastinal space may occur from the esophagus or from the tracheobronchial tree. It is a possible complication of such respiratory disorders as asthma, influenza and pneumonia. Violent coughing associated with these illnesses is responsible. It may follow heavy lifting or straining at stool. Air escaping, usually from the tracheobronchial tree, dissects along the interstitial tissue and bronchial vessels to the hilum of the lung. There may be associated pneumothorax. Accompanying substernal pain may be severe, radiating to the neck and arms and suggesting the symptoms

may compress the mediastinal structures to a dangerous degree, making immediate surgical relief imperative. The cervical fascial layers should be divided, loosely packed open and, if necessary, their abnormal air content evacuated by suction pump.

Crushing injuries to the chest wherein fluid, blood, lymph and inflammatory exudate quickly accumulate give the patient a most characteristic appearance. There is a progressive increase in swelling over the soft tissues of the thorax and in those of the neck and face. The eyelids may swell so as to obscure the eyeballs. There are subcutaneous petechial hemorrhages and the skin may be the dusky hue of that characterizing cyanosis of varying degrees. The victim is unrecognizable. Shock both from the primary injury and from the developing hypoxia must be combated.

The measures to control hypoxia due to whatever cause must always be kept in mind. They are maintenance of a clear airway by suction, by bronchoscopy or by tracheostomy; oxygen administration; paravertebral procaine block; correction of the structural deformity and incision and drainage for relief of abnormal pressure, plus other measures for shock prevention.

The anatomy of the cervical mediastinum, as well as the thoracic mediastinum, and the relationship of the deep cervical fascia of the neck to the thoracic inlet are important in the consideration of the management of air and inflammatory fluid accumulation.

MEDIASTINITIS

The principal routes by which infection involves the mediastinum are, in the order of their frequency: extension directly from structures within the mediastinum, extension from the neck by way of the fascial planes and through lymphatic drainage. The advent of chemotherapy and of the many new antibiotics has completely changed the course, the seriousness and the outcome of acute mediastinal infections. Whereas at one time pulmonary infections leading to suppurative pleurisy and in turn suppurative mediastinitis, both diffuse and localized, were not uncommon, today these processes are relative rarities and seldom are presented for their definitive care. The most frequently encountered cause of acute mediastinitis today is from foreign body trauma either through ingestion or by accidental injury in the many diagnostic and therapeutic endoscopic procedures. It is no reflection on the techniques themselves. In the

vast majority of instances, it mirrors the increasing use of these diagnostic measures and their inevitable risk.

In considering mediastinitis arising from infected mediastinal lymph nodes, one visualizes the acute or subacute lymphadenitis seen, for example, in tuberculous infections. Obviously, mediastinal as well as other lymph nodes may be involved in the drainage from any focus of infection. This is a localized process. It may go on to become chronic. An example is seen in the formation of traction diverticula due to inflammatory contraction and outpouching of the esophageal wall about chronically inflamed, even calcified, lymph nodes. Under certain circumstances, these diverticula have perforated. Whereas it is conceivable that they might produce spreading, phlegmonous mediastinitis, experience has been that the inflammatory process in the mediastinum has prevented such spread. However, the intrapleural manifestation of disease such as empyema and even tension pneumothorax may predominate.

Acute inflammatory disease such as arises from infected teeth or from retropharyngeal abscess has in the past spread to the mediastinum from the cervical region along the fascial planes. It is important to understand the basic pathologic processes, the manifestation of their spread and the most effective measures in their treatment even though modern therapy has almost entirely altered the index of their danger.

Visceral perforation in the neck, as well as within the confines of the thorax, is similarly minimized as a serious threat to health through the prompt and adequate employment of antibiotics. Here too, and of even greater importance, must the proper therapeutic measures be understood. Antibiotic sensitivity through previous employment, often for trivial affections, has led to a definite percentage of the population becoming sensitized. Whereas new antibiotics are being developed yearly, unless desensitization means are likewise developed there will be times when antibiotic usage will be valueless and even dangerous. For comparison, one must keep in mind the wisdom of the philosophy expressed by Evarts Graham about the treatment of thoracic empyema. In general, it was to this effect: when the infecting organism is relatively nonvirulent almost any treatment suffices, but when the infecting organism is virulent then only will the best treatment be effective.

As in thoracic empyema, the best treat-

Figure 1 The mediastinum is presented in sagittal view, it is divided into anterior and posterior compartments. The anterior division is further subdivided into superior and inferior spaces. The midmediastinum is considered as a portion of the posterior compartment.

The Roman numeral ovoids designate the more common location of specific tumors. In the region of ovoid I should be found the tumors of the anterior superior mediastinum which would be largely those of thyroid and thymic origin. Dermoids would occupy this area, too, as well as the area of ovoid II. Also, in ovoid II would be the pericardial cysts, lipomas and the more rarely encountered new growths. In ovoid III would be the tumors at the hilum of the lung and in ovoid IV the posterior mediastinal tumors which, as has been stated, are principally neurofibromas, but which may also be chondromas, chondromyxomas and chondrosarcomas. Not illustrated are those lesions in the thorax which occur in the mediastinum through upward extension of intra-abdominal processes. These may be foramen of Morgagni diaphragmatic hernias which are confused with anterior mediastinal tumors, and partial eventions of the diaphragm containing spleen or liver which are confused with mediastinal tumors in more posterior locations.

of coronary occlusion. Dyspnea and cyanosis may be present. Fortunately, the characteristic to and fro crunching or clicking sound audible over the precordium, synchronous with respiration (Hamman's sign), is distinctive.

Trauma to the esophagus or tracheobronchial tree, either direct or by increase in intraluminal pressure, is the most common cause of mediastinal emphysema. The reaction associated with the escape of intra-esophageal content is more damaging than that from air alone. On the other hand, a sizable rent in a major bronchus will allow the escape of enough air to alter seriously the pressure relationships within the mediastinum to the point of critically embarrass-

ing the normal function of its contents. The more peripheral the source from the tracheobronchial tree, the slower is the accumulation of air. There may be no serious embarrassment due to pressure change, yet distortion of the normal body appearance due to subcutaneous emphysema may be extreme. Crepitation, the sign of crackling of the subcutaneous tissue on palpation, will be detected at times as far as the terminal phalanges of the fingers. The neck and face may be enormously swollen, yet the interference with respiration and circulation may be quite minimal.

On the other hand, the rapid escape of air along the fascial planes of blood vessels, together with the extravasation of fluid,

ment is adequate drainage. For infection above the level of the fourth dorsal vertebra, cervical mediastinotomy will be adequate. Infections whose level is below that of the fourth dorsal vertebra will require mediastinotomy either through a posterior approach or through a transpleural approach (Fig. 2).

The most effective treatment begins with early recognition. The diagnosis is suspected if, in a patient whose temperature, pulse and leukocyte count are normal before an endoscopic procedure, there develops thereafter a substernal, epigastric or shoulder pain with

an elevation of temperature of 1° or 2° F. and of the leukocyte count from levels of 11,000 to 25,000 cells per cu. mm. of blood. If, for several hours, this pain persists and is made worse by deep inspiration, then the suspicion is clinically confirmed. The additional physical signs which may be present are fullness in the cervical region if the perforation has been in the upper dorsal or lower neck level, tenderness, edema, induration and crepitation due to subcutaneous emphysema.

Roentgenograms made with a portable apparatus are of little help and should not be

Figure 4. The lateral roentgenograms of the neck are further explained by the illustrative drawings. On the left, it is noted that the width of the tracheal column of air is greater than the distance between the posterior tracheal wall and the anterior vertebral body. This space contains the esophagus. On the right, the space between the anterior vertebral body and the posterior tracheal wall designated as B' has been considerably widened by the presence of air and exudate due to mediastinitis. It is definitely wider than the tracheal column of air labeled A'.

Figure 2. Cervical mediastinotomy for effective drainage as low as the level of the fourth dorsal vertebra. A, Skin incision along the anterior border of the right sternomastoid muscle B, Liberal exposure of the platysma muscle before division C, Penrose drains are illustrated as having been inserted to the depth of the visceral compartment lateral to the strap muscles below and medial to the omohyoid and well into the superior mediastinum. Right-sided drainage avoids possible injury to the larger left thoracic duct.

Figure 3 A, Anteroposterior roentgenogram of the thorax illustrating a right, upper mediastinal abscess B, Oblique roentgenogram of the thorax after barium swallow, demonstrating extravasated droplet of barium in the mediastinum. C, Roentgenogram of the esophagus after barium ingestion illustrating a pharyngo-esophageal diverticulum which had been perforated at the time of endoscopy producing the abscess illustrated in A and B. It was not until after the mediastinal abscess had been drained by posterior mediastinotomy that this was recognized. This must be kept in mind as a cause of esophageal perforation when endoscopy is carried out before preliminary barium study.

ment is adequate drainage. For infection above the level of the fourth dorsal vertebra, cervical mediastinotomy will be adequate. Infections whose level is below that of the fourth dorsal vertebra will require mediastinotomy either through a posterior approach or through a transpleural approach (Fig. 2).

The most effective treatment begins with early recognition. The diagnosis is suspected if, in a patient whose temperature, pulse and leukocyte count are normal before an endoscopic procedure, there develops thereafter a substernal, epigastric or shoulder pain with

an elevation of temperature of 1° or 2° F. and of the leukocyte count from levels of 11,000 to 25,000 cells per cu. mm. of blood. If, for several hours, this pain persists and is made worse by deep inspiration, then the suspicion is clinically confirmed. The additional physical signs which may be present are fullness in the cervical region if the perforation has been in the upper dorsal or lower neck level, tenderness, edema, induration and crepitation due to subcutaneous emphysema.

Figure 5 Barium study of the esophagus and esophagogastric junction, demonstrating a fistulous tract leading from the left wall of the esophagus just above the esophagogastric junction. This is the characteristic location of so-called spontaneous perforation of the esophagus, which leads to fulminating mediastinitis. Clinically, it is frequently represented by the triad of, (1) rapid respiration, (2) abdominal rigidity and, most pathognomonically, (3) subcutaneous emphysema in the cervical region.

Figure 6 A, Barium study of the esophagus in a patient with lye stricture. B, Anteroposterior view of the thorax in the same patient with evidence of barium extravasation and clouding of the left lower thorax. These were incontrovertible evidences of esophageal perforation and mediastinitis. This patient had tried to forcefully swallow an impacted food bolus.

relied upon. The patient should be taken to the x-ray room and given a radiopaque material for fluoroscopic studies. If there is no perforation harm will not follow. If a drop-let of fluid escapes from the esophageal lumen (Fig. 3), then immediate operation should be performed. Lateral roentgenograms of the neck, in addition to revealing air in the tissue spaces, will demonstrate any change in the normal width of the space between the posterior tracheal wall and the anterior vertebral body (Fig. 4). Under ordinary conditions this should not exceed the width of the tracheal column of air. If perforation has occurred, the space is in-

creased beyond this measurement. Other roentgenologic signs include widening of the mediastinal shadow, elevation of the diaphragm and obliteration of the costophrenic or cardiophrenic angle. Small quantities of fluid may be present.

As in perforation of abdominal viscera, there is sometimes a temporary period of apparent improvement with subsidence of reaction between six and eighteen hours after injury, marked by a decrease in pain and tenderness and a lowering of the temperature and leukocyte count. This may give a false impression and cause surgery to be delayed, thereby adding to the gravity of the situation.

Figures 4, 5 and 6 serve to illustrate some of the essentials in the manifestations and treatment of mediastinitis from various causes in representative cases.

The creation of a high index of suspicion is necessary to the prompt recognition of spontaneous esophageal perforation. It may conceivably be related to peptic esophagitis. The associated pathologic processes are very much like those seen in peptic duodenitis. When perforation does occur its manifestations are explosive. X-ray examination may be inconclusive. Because of discomfort, it is difficult for the patient to cooperate so that an informative roentgenogram can be made. The "interpretive roentgenograms" in Figures 7, 8 and 9 illustrate three modes of progression from the initial perforation.

Figure 7. If escaping esophageal content is confined to the mediastinum there may be minimal pleural reaction. The mediastinal shadow may progressively widen. In these individuals detection of cervical emphysema by the discovery of crepitation is of utmost importance.

Figure 8. There may be a moderate unilateral or even bilateral pleuropneumonia inflammatory reaction if with the esophageal rupture there is perforation or extension into the pleural space or spaces. There will be the combined symptoms of mediastinitis and pleuritis.

Figure 9. The pleural manifestations may progress to the point of marked respiratory embarrassment due to the development of tension pneumothorax. The increasing intrapleural pressure from accumulated fluid, both air and inflammatory exudate, may lead to death if recognition is not prompt. Immediate thoracentesis is indicated while preparing the patient for surgical intervention.

MEDIASTINAL TUMORS

In general it can be said that tumors within the mediastinum may have their origin from one or all of the primordial germ layers or their adult derivatives which have contributed to the normal structures of the region. Heuer and Andrus have classified these tumors as follows: dermoid cysts, teratomas, cysts of entodermal and mesodermal origin, cystic lymphangiomas, echinococcus cysts, fibromas, lipomas, leiomyomas, xanthomas, chondromyxomas, chondromas, chondrosarcomas, neurofibromas, ganglioneuromas, neuroblastomas, neuroepitheliomas, benign and malignant tumors of the thymus gland, lymphosarcomas, Hodgkin's disease, endotheliomas, primary and secondary sarcomas, primary and metastatic carcinomas and, finally, goiters (Fig. 10).

Assuming that any intrathoracic new growth may be one of these, what generalizations are helpful in guiding diagnostic thought and therapy? Certainly the location of the tumor in the mediastinum helps to establish its identity. Characteristically, we know that specific tumors frequently arise

in arbitrarily designated mediastinal divisions. Perhaps the most common mediastinal tumor is the adenoma of the thyroid, when it is substernal in location (Fig. 11). It may be deeper intrathoracically than might be ordinarily suspected and may less commonly lie posteriorly in the mediastinum. It is more characteristically located anteriorly. There need not be an enlarged cervical thyroid.

The next most common anterior mediastinal tumor is the so-called dermoid (Fig. 12). Tumors of this nature containing elements of one germ layer are epidermoids, those with two layers are true dermoids and those with three germ layers represented are teratomas. It is convenient as well as profitable to consider the more usually encountered anterior mediastinal tumors in a differential diagnosis of lesions so located by x-ray examination. Tumors may arise in a given mediastinal compartment and by growth extend to occupy other mediastinal compartments, nevertheless, the point of origin is of extreme importance in determining the nature of these neoplasms. An an-

Figure 10. A and B, Anteroposterior and lateral roentgenograms of the thorax illustrating a rounded anterior mediastinal tumor in which there is a calcium deposit. C, Photograph of the gross specimen which includes the cervical thyroid above and its intrathoracic extension.

Figure 11. A, Anteroposterior roentgenogram of the chest with clouding in the right lower thorax indicative of pleural empyema. B, Anteroposterior roentgenogram of the chest with catheter instillation of radiopaque Lipiodol. The sinus tract obviously communicates with the bronchus and extends toward the midline. C, Lateral roentgenogram of the chest at the time of this diagnostic procedure, showing that the catheter passes anteriorly and that the communication is with the anterior mediastinal tumor. The empyema, in this instance, was secondary to the rupture of the dermoid tumor of the anterior mediastinum into the bronchus.

Figure 12. A, Artist's conception of the anterior approach for removal of the dermoid tumor. This patient was operated upon before the days of chemotherapy and antibiotics. B, Dermoid tumor with the characteristic hair apparent on its surface. C, Photomicrograph of the tumor, showing epidermal elements as well as mesodermal elements represented by fat cells.

terior mediastinal dermoid may become complicated through communication with the tracheobronchial tree by rupture and produce pleural empyema which will manifest itself posteriorly. Such a situation is illustrated in Figure 11, which also demonstrates the diagnostic procedures employed to establish the anterior location of the tumor, characteristically a hair-covered dermoid bathed in a sebaceous type of secretion and microscopically exhibiting evidence of its two germ-layer origin. Figure 13 presents an interesting comparison to Figure 14. The oblique view in Figure 13 indicates the relationship to the pericardium. This was established as being a so-called

spring water or pericardial (coelomic) cyst, according to the classification one chooses to follow. In contradistinction, the microscopic nature of the tumor in Figure 14 for comparison indicates that it is solid and of thymic origin.

Whereas, anatomically, the midmediastinum may not be recognized as a separate compartment, still the region about the tracheal bifurcation is the origin principally of tumors arising in the lymphatic glandular structures or metastatic to them. The lymphomas, Hodgkin's disease and the leukemias constitute one group. Among the metastatic lesions, bronchogenic carcinoma involves the regional lymph nodes which

include the carinal group. The sharpness of the carina as demonstrated by bronchoscopic examination, or by planographic view, is of considerable diagnostic significance.

The most common posterior mediastinal tumor is generally agreed to be the neurofibroma. It arises from the neurilemma sheath of intercostal nerves. These tumors undergo a malignant change and become neurofibrosarcomas. The related neoplasms of central nervous system origin such as the ganglioneuromas and neuroblastomas are also found in the posterior mediastinum. Figure 15 illustrates the x-ray appearance both in the anteroposterior and lateral views of a posterior mediastinal neurofibroma, the gross appearance of the tumor and its mi-

croscopic nature are evident. This is a benign tumor and the prognosis after its surgical removal is obviously excellent. Contrast this with the tumor illustrated in Figure 16. The working diagnosis in this instance was also neurofibroma because of the characteristic posterior location of the tumor. At operation, however, this proved to be a chondromyxosarcoma arising from the region of the intervertebral disk. Because of its malignant infiltrative nature, it was impossible to resect it completely. Death from local extension resulted. It is quite obvious that the prognosis of all mediastinal tumors depends upon their microscopic nature. This determination can only be made by exploratory thoracotomy and excision of the tumor when possible.

Figure 14. A, Anteroposterior roentgenogram of the thorax illustrating a right mediastinal shadow for comparison with Figure 13. B, Photomicrograph of the tumor establishing it as a thymoma.

The symptoms of mediastinal tumors are obviously variable, depending upon the size and origin of the tumor. Occasionally, a symptom may be pathognomonic of a particular type of tumor; for example, coughing up hair is indicative of the presence of a dermoid cyst. Certain manifestations of probable incurability are recognized. Important among these are involvement of the cervical sympathetic nerves producing a Horner's syndrome, hoarseness from recurrent laryngeal nerve invasion and elevation of the diaphragm as an evidence of phrenic nerve damage.

Certain signs, both from laboratory studies, including x-ray examination, and physical examination, are of diagnostic importance. It has long been recognized that a circumscribed, spherical tumor with smooth outline is not necessarily benign.

Hard cervical or axillary lymph nodes must be searched for and studied when they are present in association with a mediastinal x-ray shadow. The fluid level sometimes seen in anterior mediastinal tumors caused by fat floating on fluid is pathognomonic of dermoids. The use of a test dose of roentgen ray therapy as evidence in the diagnosis of a tumor has very little to offer. Except when surgical intervention is contraindicated, it should not be employed because of the associated delay.

The diagnosis of indeterminant mediastinal shadows should be carried out in a very systematic way. Careful history taking; physical examination; blood studies, including bone marrow examination; sputum for direct smear and culture, paraffin block and Papanicolaou study; appropriate x-ray examination, including planographic views; radio-

C, The photomicrograph establishes its microscopic nature as a chondromyosarcoma The prognosis in this instance was far more serious than for the benign neurofibroma illustrated in Figure 15

active iodine survey; occasionally diagnostic pneumothorax and needle biopsy, and, more frequently advocated than ever before, exploratory thoracotomy are recommended.

A tumor of the mediastinum, as any other intrathoracic tumor, should be treated as is a tumor of the breast. The exact nature of the lesion must be determined and the removal accomplished, except when obviously contraindicated.

A surgical approach by a posterolateral incision is commonly employed because it allows the most adequate exposure of the mediastinum. The disadvantage in transgressing the pleural cavity is compensated for by the adequacy of the exposure of the lesion to be resected. The level of the incision depends upon the level of the growth to be exposed. The anatomy of these incisions should be carefully studied. In the young, a rib need not be resected, but in those individuals of the middle and later periods of life, it is better to resect a rib and to divide ribs above or below in order to secure adequate working room. Airtight closure of the thorax is advisable with complete re-expansion of the lung through the use of catheter drains attached to a negative pressure apparatus. When drainage ceases and the postoperative roentgenogram discloses that the lung on the operated side is completely expanded, then the catheter may be removed and a pressure dressing applied over the point of its withdrawal from the chest wall.

More use is being made of an anterior surgical approach by sternum-splitting in-

cisions. These incisions may be made as extensions downward from the cervical collar incisions, as extensions upward from upper abdominal approaches, or as primary transverse divisions. The sternum should be carefully divided with a Lebschke knife or Gigli saw so as to protect the structures of the anterior mediastinum from inadvertent injury. The sternum may be spread over its entire length or the incision may be carried into an intercostal space if the more extensive exposure is not necessary. In so doing, it is important to protect against injury to and hemorrhage from the internal mammary arteries. The sternum may be reapproximated with multiple stainless steel wire sutures placed through its entire thickness or simply through its anterior table. The anterior fascia of the sternum can be approximated with either fine silk or catgut sutures to cover the projecting end of the wire. If there is any anticipated difficulty from retention of bronchial secretion, it is preferable to do a prophylactic tracheostomy in association with the sternum-splitting incision. This is an innocuous procedure. It is far easier and better to do it electively than ineffectively as an emergency. Because of the reported incidence of malignant change in thyroid adenomas, a word could be said for the advantage of the sternum-splitting incision wherein complete removal without morcellation can be carried out. Morcellation would tend to implant the tumor in the event that such adenomas are malignant. Nevertheless, sternum splitting should be reserved for selected cases.

Posterior mediastinotomy has been largely

abandoned in favor of the transpleural posterolateral approach. However, it has a definite place in the armamentarium of the thoracic surgeon. If mediastinotomy is to be accomplished without tearing of the parietal pleura, a long segment of the rib directly over the area to be investigated should be removed, with additional shorter resections of ribs above and below. Open pneumothorax is thus avoided.

Because tumors of the anterior mediastinum may be of thymic origin and because tumors of the thymus are frequently accom-

panied by at least incipient symptoms of myasthenia gravis, curare and its derivatives should be avoided in producing surgical anesthesia. Should respiratory difficulty develop in the postoperative period after removal of anterior mediastinal tumors, it would be well to consider the administration of ephedrine or any of the antimyasthenic drugs which have been developed.

The place of tracheostomy as an elective rather than as an emergency procedure in these surgical procedures cannot be overemphasized.

THE THORACIC WALL, PLEURA AND LUNGS

The Thoracic Wall and Pleura

By WILLIAM E. ADAMS, M.D.

WILLIAM ELIAS ADAMS was educated at the State University of Iowa but has been associated with the University of Chicago's Department of Surgery in progressive ranks since 1928. He is the chief of Thoracic Surgery and Raymond Professor of Surgery. His experimental and clinical investigations helped to establish the specialty of thoracic surgery on firm physiologic principles

PHYSIOLOGY OF THE THORACIC CAVITY

For a better understanding of the clinical features observed during the management of various abnormalities of the chest, a knowledge of pulmonary function under normal conditions and its alteration under adverse circumstances is desirable. Since pulmonary function is likely to be altered by both extrathoracic and intrathoracic operations, it is important to know the status of the lungs prior to any major operation. Although lung function assists in temperature regulation and in electrolyte balance, its principal objectives are oxygenation of the blood and removal of carbon dioxide.

Many patients have adequate pulmonary reserve to meet the body needs during illness, during and following surgery and following injury. However, in persons of advanced years or in the presence of extensive

bilateral pulmonary disease, lung function studies may be of significance in both medical management and prognosis.

Pulmonary function may be subdivided into four principal parts, namely, ventilation, distribution, perfusion and diffusion. The requirements for performance of these functions include a normal bellows action of the chest wall and diaphragm with a negative intrapleural pressure of 6 to 8 cm. of water, adequate pulmonary capacity and patent air passages for the free exchange of gases, and adequate vascular bed for perfusion of the pulmonary tissue. Under normal circumstances, a considerable reserve of pulmonary function is available for performing these activities. During rest, only approximately one-fourth of the lung capacity is required for normal pulmonary function.

Although a large percentage of patients have adequate pulmonary reserve for toler-

ating operative procedures, in individuals of advanced years or who have bilateral pulmonary disease, pulmonary reserve may be considerably reduced. Tests for determining the status of pulmonary ventilation and diffusion are important, especially when pulmonary reserve may be further decreased as a result of pulmonary resection. For ventilatory tests, the timed vital capacity (maximum volume exhaled after maximum inhalation measured in seconds) and the maximum breathing capacity (maximum amount of air inhaled and exhaled while breathing deeply and rapidly for fifteen seconds $\times 4$) have been found to be of practical value. Tests of pulmonary diffusion are considerably more complicated and difficult to make. However, in patients for whom pulmonary resection is necessary, when the results of tests for pulmonary function are correlated with clinical information they are a valuable aid both in prognosis and in planning therapy.

Interference with pulmonary function may occur during and following operations and following trauma, particularly to the chest, and it may be associated with some degenerative diseases of the lungs. Ventilation of the lung may become decreased through interference with chest wall activity as seen following an injury, or by obstruction of the air passages with foreign material such as blood, pus or mucus. Reduction of lung capacity by infection, neoplasm or injury may seriously reduce pulmonary reserve so that the diffusion of gases is inadequate. Chronic emphysema and fibrosis may materially interfere with internal mixing of gases or also produce a physiologic shunt of blood through unaerated lung and thus lead to some degree of hypoxia. Advanced stages of fibrosis with intrapulmonary vasculitis may markedly impede the flow of blood through the lungs, giving rise to cor pulmonale with varying degrees of cardiac decompensation. A knowledge of the degree of the above changes prior to pulmonary surgery is especially important in planning therapy.

Following operations on the upper abdomen or thorax, ventilation of the lung is decreased because of pain on respiration and restriction of motion of the chest wall. In pulmonary resection, there is an additional factor, i.e., decreased lung capacity. Following operation, one of three complications may result which may materially affect the postoperative convalescence of the patient by reducing pulmonary capacity:

atelectasis, pneumonitis and physiologic shunting through an unaerated lung distal to an obstructed bronchus. When mucopurulent secretions are retained in the air passages, one of the above conditions or a combination of two or more may develop. With the absorption of entrapped air by bronchial obstruction, atelectasis occurs which leads to an elevation in temperature and leukocyte count. If this condition involves an entire lung or lobe, some retraction of the mediastinum toward the side of involvement and elevation of the diaphragm on the involved side result. These findings aid materially in differentiating atelectasis from lobar pneumonia, pleural effusion, pulmonary embolism, coronary thrombosis, acute dilatation of the heart or diaphragmatic hernia. If atelectasis persists it will usually lead to pneumonitis of the obstructed lung.

When secretions intermittently obstruct a large bronchus and the air beyond the obstruction is not absorbed, a physiologic shunt occurs. This means that blood passing through that portion of obstructed nonventilated lung does not pick up oxygen. Thus, this venous blood returns to the left side of the heart, causing lowered saturation of the arterial blood oxygen. The resultant hypoxia may be sufficiently great to produce cyanosis. Since only approximately one-fourth of the lung capacity in normal individuals is necessary to oxygenate the blood adequately, if dyspnea and cyanosis accompany retained bronchial secretions, a physiologic shunt rather than atelectasis is present. The principles of management of these three conditions may be briefly enumerated as follows: *prophylaxis* should include early ambulation, postoperative breathing and coughing exercises, avoidance of restriction of respiration and the use of various aids for removal of excess secretions; *active therapy* requires stimulation of cough, removal of secretions by catheter suction or bronchoscopic aspiration, the use of expectorants postoperatively and the employment of tracheotomy when the patient is extremely ill and unable to help himself in eliminating secretions.

During intrathoracic operations on the normal chest, the lung on the side of operation tends to collapse because of its normal elasticity. In order to maintain adequate ventilation of the lung and diffusion of gases during surgery, a mild intratracheal positive pressure is necessary in the majority of patients. This may be obtained by admin-

istering oxygen and anesthetic gases through a snug-fitting face mask or by means of an endotracheal catheter. By properly employing either of these methods, ventilation of the lungs for maintenance of normal blood oxygen and pH levels can be adequate.

INJURIES OF THE THORAX

Injuries of the thorax may vary considerably in type and in degree of severity. In military casualties, as well as in persons injured in automobile and industrial accidents, wounds of the thorax have constituted one of the major causes of death. During World War I, 20 to 30 per cent of the deaths on the field of battle resulted from this cause. Only 4 to 8 per cent of the total wounded admitted to the clearing stations had chest injuries. Early mortality among those seen at advanced stations who had escaped immediate death was 25 per cent. Since fatalities usually occur early following a chest injury, it is indicated that prompt first-aid measures may materially reduce the rate of mortality. This was proved to be a fact for, during World War II, when first-aid measures were given near the front lines to men having chest injuries, deaths from these wounds were reduced to only a small fraction of those occurring during World War I. In the management of severe wounds of the chest, shock and hemorrhage from additional sites must be kept in mind as likely causes of the presenting clinical features. Disturbance of cardiorespiratory function, however, may prevent improvement following adequate treatment of shock due to other causes.

For convenience of discussion, wounds of the thorax may be divided into nonpenetrating injuries in which only the chest wall is involved, without an opening into the pleural cavity, penetrating injuries of the chest in which the entire chest wall as well as the pleura is involved, perforating injuries of the chest in which the entire thorax has been traversed by a foreign body, and blast or concussion injury of the lung in which damage of the pulmonary tissue was brought about by sudden exposure of the chest to extremely high pressure within a small enclosed area.

Injuries of the thorax may threaten life because of shock, hemorrhage, alteration of cardiopulmonary function and infection. Early first-aid measures of most importance are administration of oxygen, control of hemorrhage, correction of physical disturbance of cardiopulmonary function, replace-

ment of blood loss by the use of whole blood or plasma and prevention of infection.

Chest Injuries Requiring Immediate Attention. *Open or sucking wound with pneumothorax.* The ill effects accompanying this type of wound are chiefly those due to disturbance of cardiopulmonary function. The lung on the side of injury becomes collapsed and airless, the mediastinum deviates toward the opposite side and the contralateral lung becomes hypoinflated. If the opening through the chest wall is larger than the size of the trachea, the condition is usually incompatible with life. Paradoxical respiration develops in which the mediastinum swings from side to side with respiration, thus preventing normal or adequate gaseous exchange in the remaining inflated lung. In addition to the ill effects on pulmonary function, hemorrhage from the chest wall or lung may add to the clinical picture. Dyspnea and cyanosis in varying degrees of severity, cough and hemoptysis are usually present.

First-aid measures should include immediate closure of the opening through the chest wall by whatever means are available, thus converting the open pneumothorax into a closed pneumothorax. Aspiration of air from the pleural cavity on the injured side will increase the pulmonary capacity and give some immediate relief of symptoms unless serious hemorrhage has occurred. Definitive treatment, when available, should include hemostasis, débridement of the wound with removal of foreign material from the chest wall or intrathoracic area and removal of air from the pleural cavity by continuous suction drainage after closure of the chest wound. Replacement of blood loss and the use of oxygen and antibiotics are an important part of the treatment.

Tension pneumothorax. This condition is produced by a penetrating wound of the chest, in which the lung is injured by a fractured rib or a foreign body. As air escapes into the pleural cavity and is trapped, the pressure within the pleural cavity gradually increases, thus collapsing not only the lung on the side of injury, but, to somewhat lesser extent, the lung of the opposite side (Fig 1). In addition to the deleterious effects from the markedly reduced pulmonary capacity, symptoms may also be due to hemorrhage within the pleural cavity. Ventilation of the opposite aerated lung is also diminished because of deviation of the mediastinum toward the contralateral side. This condition is recognized by the presence

of dyspnea, cyanosis and increased peripheral venous pressure. Physical findings are self-explanatory.

Management of tension (pressure) pneumothorax includes the use of continuous suction applied to the pleural cavity through an intercostal catheter for re-expansion of the lung and replacement of blood loss if hemorrhage has occurred. A small foreign body in the lung may be inconsequential and require no therapy. Foreign bodies over 1 cm. in size, however, especially when located near larger vessels, should be removed when facilities are available. The use of oxygen and chemotherapy is valuable in treating these subjects.

Unstable chest wall, "flail chest." Multiple fractured ribs are frequent; however, a double fracture of several ribs occurs infrequently. When several ribs are broken in two places, covering a segment of the chest wall, this area may become unstable. If the region is sufficiently large and tends to move inward on inspiration, thus interfering with ventilation of the lung, the condition is called a "flail chest." This injury usually results from a crushing blow to the chest by a flat object. It is accompanied by hemorrhage into the chest wall as well as into the pleural cavity. Lacerations of the underlying lungs

by the fractured ribs with resultant pneumothorax may occur. The clinical features attending this type of injury are due to interference with ventilation of the lung, decrease in pulmonary capacity from hemothorax and collapsed chest wall and loss of circulating blood volume.

In simple fracture of the rib, paravertebral blocking of the involved intercostal nerve roots with procaine is the treatment of choice. Control of pain by this method is preferable to strapping the chest with tape, since the latter tends to interfere with respiratory activity. Early therapy for flail chest entails stabilization of the chest wall by whatever means are available. Adequate ventilation of the remaining functioning lung tissue is then re-established. If a large segment of the chest wall is involved, massive collapse of the lung on the ipsilateral side may occur. This may be both from compression of the chest wall and from bronchial obstruction by blood or secretions (Fig. 2). Definitive treatment entails elevation and stabilization of the flail segment by traction. By this means, the underlying collapsed lung will be re-expanded and the normal size of the thoracic cage will be re-established. Additional therapy should include replacement of blood loss by transfusion and removal of air and blood from the pleural cavity. Oxygen and antibiotics should be used as indicated.

Figure 1 Tension pneumothorax X-ray appearance of the chest in tension (pressure) pneumothorax in a twenty-eight year old woman who had developed a bronchopleural fistula secondary to cystic disease of the lung. Note the marked shift of mediastinal structures to the left with complete collapse of the right lung and partial collapse of the left lung

Figure 2 Flail chest. A "double fracture" of the right second to sixth ribs, inclusive, with massive collapse of the right lung is shown. The chest wall was stayed in as a result of an automobile accident. Note also some shift of the upper mediastinal structures to the right, indicating obstruction of the air passages on that side. The drawing was made from an x-ray film of the chest of a fifty-four year old woman made shortly following the accident.

Figure 3. A, X-ray appearance of the chest of a thirty-two year old man six and one half months following an injury which caused a large hemothorax. The blood was not adequately removed. A layer of fibrous tissue "peel" developed over the lung and chest wall pleura with subsequent contraction of the chest wall. Pulmonary capacity as well as ventilatory function was greatly reduced. B, X-ray appearance following removal of "peel" covering the lung and chest wall. Note normal re-expansion of the lung. Both pulmonary capacity and ventilation of the lung were improved.

Massive collapse of the lung (atelectasis). Atelectasis may occur as the result of bronchial obstruction by blood or mucopurulent secretions or from compression of the lung by air or fluid within the thoracic cavity or by a collapsed flail chest resulting from a crushing injury of the chest wall. Since the clinical features of this condition are quite readily recognized, there is usually little difficulty in diagnosis. Treatment consists of eliminating the cause and management of the associated pathologic process as described above.

Hemothorax. Chest injuries may be accompanied by serious hemorrhage into a pleural cavity from one of three locations—an internal mammary artery, an intercostal artery or the lung. Since bleeding within the pleural cavity is "hidden," it may reach considerable proportions before its seriousness is evident. By this time, the patient usually presents the usual manifestations of severe shock due to blood loss, such as cold clammy skin, pallor, rapid thready pulse and lowered blood pressure. In addition to the usual symptoms caused by severe hemorrhage, local findings over the involved chest lead to the establishment of a correct diagnosis.

Treatment consists of replacement of blood loss, oxygen and antibiotic therapy and removal by aspiration of blood from the pleural cavity. If the blood pressure level

continues to drop after replacement of blood loss by transfusion, continued bleeding from a systemic artery is most likely present. Exploration of the wound or intrathoracic structures with control of bleeding is then indicated. If bleeding has stopped after replacement of blood loss, removal of all blood from the pleural cavity by aspiration should be completed within twenty-four hours. In the event that clotting of blood has occurred, one of two types of management should be followed: open thoracotomy with removal of clots and re-expansion of the lung or drainage of the pleural cavity through a catheter placed in the chest wall and the local use of enzymes for liquefaction of the clotted blood. If trauma is extensive, exploratory thoracotomy is to be preferred, since traumatized lung can then be removed or repaired. When a hemothorax persists any considerable time, a fibrous tissue "peel" forms over both the parietal and visceral pleurae. After this has occurred, an open operation and removal of the "peel" along with the remaining clotted blood and serum are necessary for re-expansion of the lung (Fig. 3).

Chest Injuries in Which Infection Is Likely to Occur. Contaminated and lacerated wounds. Therapy in these patients consists of careful débridement combined with the administration of antibiotics and sulfonamides. When the pleura is involved,

open thoracotomy is indicated and closure is made, allowing for continuous suction drainage of the pleural cavity by catheter.

Foreign bodies. Since foreign bodies are apt to carry particles of clothing or other foreign material into the chest, infection of the pleura or other structures is apt to occur. Therapy will include measures used in contaminated wounds. In addition, the size and location of the foreign body as well as the presence of infection will determine whether the object should be removed.

Lower chest injuries involving the upper abdomen. Since the large bowel and stom-

ach are above the lowermost level of the lung on the left side, penetrating wounds in this region are apt to be accompanied by sepsis, as well as blood loss from injury to the spleen. Exploration of the upper abdomen and lower thorax is indicated and the damaged organs and tissues are treated as required.

Chest Injuries Not Usually Demanding Surgery. Subcutaneous and mediastinal emphysema. The seriousness of this condition is usually more apparent than real. The emphysema may result from penetrating, non-penetrating or crushing injuries of the chest.

Figure 4. Subcutaneous and mediastinal emphysema A and B, X-ray appearance of the chest, front and side views, of a forty-four year old man following the development of mediastinal and subcutaneous emphysema. This resulted from elevated pressure within the chest produced by repeated attacks of severe coughing caused by bronchial pneumonia. C and D, Photographs of patient during the presence of emphysema and after it had disappeared. Dissection by the air through the subcutaneous tissues and along fascial planes extended up to the scalp and down to the pelvis. No treatment was required other than that directed toward control of the cough and the management of the pulmonary infection.

Air from an injured lung may dissect through the damaged chest wall to all layers of the soft tissues. In crushing injuries, air may escape along the bronchovascular roots of the lung to the mediastinum and pass up into the base of the neck and thence over the chest wall and up over the face and scalp (Fig 4). Unless the air within the mediastinum tends to compress the large veins, such as the superior vena cava, this condition is usually not serious and requires only control of the etiologic factor. The condition is usually easily recognizable, since palpation demonstrates a crackling sensation due to the presence of air beneath the skin.

Traumatic asphyxia. This condition is caused by sudden compression of the thorax with the resultant forcing of venous blood back into the capillaries of the upper extremities, head and neck. This produces a bluish-purple discoloration of the involved area. Although the appearance suggests an alarming condition, actually little or no alteration of cardiopulmonary function occurs. Proper management includes rest and the treatment of associated lesions.

Blast injury of the lung. This injury usually results from sudden severe compression of the chest by rapid elevation of atmospheric pressure about an individual in a confined area, such as a tunnel or a narrow street bordered by tall buildings. Cough with mild hemoptysis, and symptoms and findings of mild shock and cerebral concussion are commonly present. Recovery usually occurs following a regimen of rest, oxygen therapy and adequate sedation. Death has

occurred, however, possibly from coronary air embolism due to air being forced into the coronary vessels.

Closed pneumothorax. When this condition is due to a penetrating or crushing wound of the chest, no symptoms may occur unless the trauma has been of such a severe degree as to produce collapse of the major portion of an entire lung. On physical examination the diagnosis is obvious and re-expansion of the lung may be accomplished by aspiration of the air. If the lesion recurs because of the presence of a bronchial fistula, continuous suction through an intercostal catheter usually produces permanent re-expansion of the lung.

CONGENITAL ANOMALIES OF THE THORAX

Malformations of the thoracic cage are not uncommon, however, the majority are of no clinical significance. Occasionally anomalies are incompatible with life, such as absence of the diaphragm, an extremely high eventration of the diaphragm or partial absence of the thoracic wall which may be associated with ectopia cordis. Anomalies which have no particular clinical importance include forking of a rib anteriorly, fusion of two ribs and absence of a portion of a rib. Anomalies which may be of surgical significance are pectus excavatum (trichterbrust, funnel chest), cervical rib and hernia of the lung.

Pectus Excavatum. This anomaly consists of a congenital deformity of the sternum and adjacent cartilages and anterior segments of ribs. At times, there is associated a

Figure 5. Pectus excavatum. Drawing of lateral (sagittal) and cross-sectional view of deformity of chest wall showing marked encroachment upon area (space) normally occupied by the heart. The heart is rotated farther into the left side of the chest as the deformity increases.

Figure 6. A and B, Front and side x-ray appearance of a nineteen-year-old male with pectus excavatum. Note marked reduction of anteroposterior dimension of the mediastinum to less than 2 inches and some deviation of cardiac shadow to the left. C and D, Postoperative appearance following surgical correction of defect. Note increase in A-P dimension of mediastinum. Also note brace placed over the chest anteriorly to aid in maintaining elevation of sternum. E, Photograph showing scar and normal contour of chest wall following surgery.

varying degree of scoliosis. The deformity usually begins at the junction of the first and second portion of the sternum and extends downward to and including the xiphoid process which is at the greatest backward extension of the deformity (Fig. 5). The significance of this deformity may be because of its psychologic effect, or its interference with cardiopulmonary function. In severe cases, the distance between the anterior surface of the thoracic vertebrae and the posterior surface of the sternum may not be more than 2 or 3 cm. (Fig. 6). Thus, the heart is rotated to the left and at times its activity is affected.

Treatment of this condition by a plastic operation for elevation of the sternum and adjacent involved cartilages and ribs is justified when the deformity either interferes with cardiopulmonary activity or is likely to interfere later if the degree of deformity is increasing. The operation is also indicated when the deformity is a psychologic handicap to the individual. The outlook following surgery is favorable.

Cervical Rib. Although in a high percentage of its subjects this deformity is of no clinical significance, at times it gives rise to a condition known as scalene syndrome. The

ly usually occurs bilaterally, but clinical

manifestations may involve only one side. These consist of numbness and tingling and a decrease in the normal temperature of the hand and forearm of the affected side. The clinical picture is caused by an interference with the blood supply to the arm resulting from compression of the subclavian artery and a portion of the brachial plexus between the scalenus anticus muscle and the cervical rib. Treatment consists of liberation of the constriction by surgical division of the scalenus anticus muscle. Favorable results following the operation usually can be anticipated.

Hernia of the Lung. This is a very uncommon condition. It may be congenital or may develop following trauma to the chest wall. The congenital type is a true hernia, with a sac of parietal pleura into which the lung protrudes, it occurs most commonly near the sternum or vertebrae through an intercostal space. The acquired type may follow an injury to any part of the chest wall, the lung prolapsing through a defect produced by the trauma.

The usual symptoms are a bulging mass, pain over the local area and cough. The size of the mass increases on coughing or straining. The cough is usually nonproductive but may bring forth bloody sputum. Incarceration

tion and strangulation of these hernias have been reported.

Physical examination reveals a soft, crepitant, bulging mass which suddenly increases in size on coughing. A bony or fibrous ring may be felt through which a finger may be inserted into the chest cavity. The diagnosis is easily made.

Since these hernias rarely heal spontaneously, treatment consists of freeing the contents of the hernial sac and closure of the defect in the chest wall by a plastic operation.

INFLAMMATIONS AND TUMORS OF THE CHEST WALL AND PLEURA

Inflammations of the Chest Wall. Subpectoral abscess. A subpectoral abscess, or subpectoral phlegmon, is an uncommon although serious lesion and because of its location beneath heavy-bellied muscles it is frequently misdiagnosed in its early development. The infection begins in the subclavicular glands at the extreme apex of the axilla and is usually caused by a hemolytic streptococcus secondary to an infection or injury of the hand, arm, axilla or breast. It also may follow an injury of the chest wall or of the supraclavicular fossa.

The subclavicular glands lie adjacent to the axillary vein high in the axilla and just beneath the costocoracoid membrane. When the infection extends outside of these glands, it spreads downward and outward beneath this fascia and at times may extend posteriorly around the chest wall to the subscapular region.

Since the infection lies deeply hidden from the surface, local symptoms and findings are insignificant in the early stage and are usually preceded by fever, chills and general malaise. Pain in the shoulder and arm, especially on adduction or rotation, rigidity of the pectoralis major muscle and a sensation of tenderness or pain near the middle of the clavicle are the first local manifestations. Examination reveals no early local abnormalities, but later, swelling and a fullness near the outer inferior border of the pectoral muscle with tenderness over this area are noted. Much of the swelling may be due to edema and the lack of fluctuation is misleading, often delaying the diagnosis.

Treatment consists of incision and adequate drainage along the outer inferior margin of the pectoralis major muscle. Additional drainage by division of the muscle fibers beneath the clavicle may be necessary.

Sulfonamides, penicillin and streptomycin are helpful in controlling the spread of the infection but should not be relied upon as a substitute for surgical drainage. Because of the location of the abscess, pyemia and septicemia are not uncommon. The condition is always serious and the prognosis must be guarded.

Subscapular abscess. A subscapular abscess is much less common than a subpectoral abscess and usually produces few local or systemic symptoms. Although caused by pyogenic organisms, it may present the appearance of a cold abscess. At times it is differentiated from tumors only by the presence of fluctuation. Treatment consists of adequate drainage after determination of the etiologic organism by aspiration.

Acute osteomyelitis. Acute osteomyelitis of a rib may result from drainage of an empyema due to trauma or general staphylococcal infections. With the exception of the last mentioned, the systemic involvement is much less common than that produced by infection in other bones. Involvement of the cut end of the ribs following rib resection for draining an empyema is uncommon and produces no systemic reaction. Occasionally an entire rib may become involved and sequestrate. Surgical removal of the sequestrum is followed by complete healing. Osteomyelitis following trauma to a rib produces no special problem and is treated in the usual manner for this lesion. Osteomyelitis of the sternum is much less common but when present carries a high mortality.

Typhoid osteomyelitis of a rib is rarely seen, since the incidence of typhoid fever has been reduced. The local condition may not appear for months or years after an attack of typhoid fever, however, a history of an attack is usually present. Locally a fluctuant swelling develops, but signs of an acute inflammation are lacking. Its recognition is important in order to prevent spread of the organisms before the diagnosis is made. Typhoidal osteomyelitis must be differentiated from tuberculosis, syphilis, sarcoma and chronic pyogenic infections of the rib. Aspiration and culture along with a history of typhoid fever are usually sufficient for establishing the diagnosis. Treatment consists of surgical excision of the involved bone.

Tuberculosis. Tuberculosis of the sternum, ribs and cartilages is seldom seen since pulmonary tuberculosis has been brought under better control. It may develop by one of two methods—either by direct extension

from tuberculous glands lying just outside the parietal pleura, usually near the sternum, or by hematogenous spread from an active tuberculous lesion elsewhere in the body. The former route is probably the much more common, since in many of the patients the tuberculous infection is around the rib or cartilage, with no evidence of infection within these structures.

Although this infection may occur at any age, it is commonest during middle life. The lesion presents local manifestations similar to those produced by cold abscesses elsewhere. There is little evidence of local inflammation, a fluctuant nontender swelling indicating its presence. If it is allowed to progress, necrosis of the skin occurs, with sinus formation. The infection may, however, extend quite some distance along a rib or cartilage before sinuses develop. Aspiration of the swelling reveals thick, curdy pus. If a sinus is present, injection of a radiopaque material and x-ray examination of the chest will aid in determining the limits of the involvement.

Treatment consists of wide surgical excision of the involved rib or of the entire cartilage, if the latter is involved. Streptomycin has been found effective in the treatment of tuberculous sinuses when no foreign body is present. In the absence of sinuses or secondary infection, closure of the wound without drainage is indicated. Supportive treatment as for tuberculosis elsewhere is helpful.

Actinomycosis. Actinomycosis of the chest wall is practically always secondary to actinomycosis of the lung or intestine. In the former, the process extends outward through the pleural cavity, and in the latter, extension is up through the diaphragm. Since this infection respects no tissue boundaries, it involves all structures of the chest wall and slowly produces a brawny induration in the soft tissues, with considerable swelling and edema. A productive cough, usually with hemoptysis, and local pain and tenderness are experienced along with the constitutional symptoms of fever, weakness, sweats, anorexia and loss of weight. If the disease process is allowed to continue, discharging sinuses are produced.

This condition may be mistaken for tuberculosis of the chest wall or tumor of the lung with secondary invasion of the chest wall. The diagnosis is established by the finding of sulfur granules in the exudate and the ray fungus on staining material removed by aspiration or biopsy technique.

Treatment consists of wide excision of the involved parts, usually performed best in several stages. The use of thymol and potassium iodide by mouth and thymol locally has been of definite benefit in some subjects. More recently, penicillin has been found to be much more effective in the majority of patients. The prognosis must be guarded in advanced lesions; however, the use of adequate amounts of penicillin has greatly improved the outlook for these patients.

Inflammation of the Pleura. Acute empyema. Inflammations of the pleura are always secondary to inflammation of the lung and parietes of the thorax or to trauma. With the advent of chemotherapy for the treatment or prevention of pneumonia, pyogenic empyema as a complication of pneumonia is seldom seen. Likewise, the clinical picture is no longer characteristic as was the case before specific therapy was available. This condition is seen more commonly today as a complication of subphrenic abscess, lung abscess or bronchiectasis or following trauma. The causative organism in empyema as a complication of pneumonia is usually a pneumococcus or a streptococcus. With another etiologic basis, it may be one of the two above or one of a fairly large variety of either aerobic or anaerobic organisms.

In the early stage of this infection, the pleural exudate is serous in nature and may occupy the entire pleural cavity or only a limited space (encapsulated empyema). More frequently, it occupies the lower portion of the pleural cavity, the apex of the lung becoming attached to the upper chest wall. As fibrin deposition occurs and inflammatory cells, such as lymphocytes, leukocytes and endothelial cells, increase, the exudate thickens. This occurs much more rapidly with pneumococcal than with streptococcal empyema. As this process continues, the exudate becomes frank pus and in reality an abscess of the pleural cavity occurs. With this development, the lung becomes adherent to the chest wall at the edges of the involved pleural space. In pneumococcal inflammation, this process requires five to seven days to develop, whereas in the presence of streptococcal infection or other aerobic and anaerobic organisms, it may require two or three weeks or longer.

The clinical manifestations of empyema thoracis are those of an inflammatory process in addition to those of a partially collapsed lung. Fever and leukocytosis with some pain in the involved area are characteristic. Be-

cause of the presence of pain or the large size of the pleural space involved, dyspnea and elevation in pulse and respiration occur in varying degrees. Examination of the chest reveals decreased motion as well as decreased to absent breath sounds on the involved side. The percussion note is dull to flat and cardiac dullness may be shifted to the opposite side. Tubular breathing and rales are not infrequently present adjacent to the area of involvement.

In view of the usual presence of an etiologic factor, the diagnosis of empyema thoracis is not difficult. An x-ray film of the chest, exposed with the patient either sitting or standing, will reveal an opacity in the region of involvement. If this is in the lower portion of the pleural cavity, the opacity will extend outward and upward as a curved shadow along the chest wall. When the empyema is encapsulated, the shape and size of the opacity are quite variable and this lesion may be confused with lung abscess or a tumor with secondary infection. Fortunately, the encapsulated type of involvement is seldom seen and thus this difficulty in diagnosis is not often confronted.

When an empyema is suspected, thoracentesis should be performed to confirm the diagnosis. If the empyema cavity extends to the base of the pleural space, aspiration is made through the seventh intercostal space in the postaxillary line. If, during the procedure, a cough is incited or exacerbated, the procedure should be discontinued until the cough is controlled by sedation.

Once the diagnosis of empyema is established, a knowledge of its extent and location of involvement is desirable. For this purpose, a diagnostic pneumothorax is induced by introducing air into the empyema cavity following the removal of exudate. In order to determine the causative organism, smears and cultures of the removed exudate should be made in order to plan proper therapy.

The treatment of acute empyema will vary somewhat according to the etiologic basis and the causative organism. In addition to chemotherapy, methods of management include aspiration, closed catheter drainage and open drainage. Chemotherapy, according to the sensitivity of the organisms, should be instituted immediately if it is not already in use. If the empyema has already reached the abscess stage when diagnosis is made, adequate open dependent drainage is the treatment of choice. This can be readily obtained by the resection of a

segment of rib in the most dependent portion of the cavity, with the patient under local anesthesia. An adequate opening must be maintained for the free drainage of exudate until the cavity is obliterated. The principles of therapy at this stage of the disease are the same as those for a pyogenic abscess elsewhere in the body. Prior to the formation of frank pus, repeated aspiration by means of thoracentesis or closed suction drainage through the use of an intercostal catheter introduced into the empyema cavity should be employed. In this way, deleterious effects due to an open pneumothorax, with perhaps deviation of the mediastinum toward the opposite side, are avoided during the stage when severe toxic manifestations from the primary cause of infection are present. If treatment is started by aspiration or the closed type of drainage, this should be changed to open drainage when the exudate becomes purulent. When repeated thoracentesis or closed drainage by catheter is utilized, introduction of the needle or trocar through the chest wall should be made at the upper edge of a rib in a dependent location. In this way, intercostal vessels and nerves will not be traumatized. This procedure can be carried out with the patient under local anesthesia and in a semisitting position in bed or on an operating-room table. Various irrigating solutions have been of benefit in some patients, however, the principal object is to obtain adequate drainage. In addition to chemotherapy and drainage of the empyema space, the use of blood transfusions, oxygen therapy and improvement of the nutritional state are important adjuncts to proper management.

When a bronchopleural fistula develops during the acute stage of empyema, serious disturbance of cardiorespiratory function may occur because of tension pneumothorax as seen in Figure 7. Continuous suction drainage through an intercostal tube or open drainage as indicated will give immediate relief.

The prognosis of empyema will depend largely upon the etiologic factor if adequate and prompt therapy is administered. When this condition occurs as a complication of pneumonia, the prospect of a cure is excellent. Empyema as a complication of lung abscess or bronchiectasis may take on a serious aspect and prognosis must be guarded.

Staphylococcus empyema. *Staphylococcus aureus* is the only organism involving this region which is not controlled by the most

commonly used antibiotics and, therefore, more attention is being focused upon it. Staphylococcus empyema occurs much more frequently in young children and in elderly people and may be unilateral or bilateral. The disease is characterized by rapidly developing toxicity with chills, fever and dyspnea and at times cyanosis. Being bronchial pneumonia in type, early pleural involvement is the rule. The rapid progressive development of pleural effusion unresponsive to the usual antibiotics is presumptive evidence of a staphylococcus infection. However, culture of aspirated pleural fluid is necessary for a definite diagnosis. Because of the rapid necrotizing effect on the lung, early effective management is mandatory. Multiple lung ab-

cesses, frequently with bronchopleural fistula and resultant pyopneumothorax, are commonly seen in inadequately managed cases. Multiple, smaller lung abscesses may coalesce, leading to pneumatocele formation.

Treatment consists of chemotherapy, evacuation of pleural exudate and supportive measures. Although a number of antibiotics have been used alone or in combination for this infection, the most effective have been Chloromycetin with erythromycin and Chloromycetin with novobiocin. These drugs should be used in full therapeutic amounts and continued for two weeks following recovery. Repeated removal of pleural exudate by thoracentesis frequently leads to pocket formation, inadequate evacuation and com-

Figure 1. Radiographs of an eight-year-old girl with pyopneumothorax and pleural fistula. This patient experienced marked toxicity. A and B show the initial manifestations of toxicity. C and D show the chest after open drainage of the empyema. The cavity is filled with radiopaque material remain-

plications. Thus, unless satisfactory results are obtained with one or two pleural taps, early intercostal tube drainage by suction as soon as the diagnosis has been made is the procedure of choice. Supportive measures include the judicious use of oxygen, salicylates and sedatives and maintenance of electrolytic and water balance. With prompt adequate management, the prognosis is good. If treatment is delayed or inadequate, open thoracotomy to remove fibrous tissue peel or to obtain adequate drainage may be necessary, and with this is an associated increase in morbidity and mortality.

Figure 8 shows x-rays of the chest of an infant of ten months following admission to the hospital with fever, dyspnea and cough of three or four days' duration. The patient had been given penicillin. The patient was found to have a temperature of 40° C., was dyspneic and presented crepitant rales in the midzone region of the left lung poste-

riorly. There was a hemoglobin of 12 gm. and a white blood count of 14,800. A diagnosis of pneumonia of the left lung was made and the patient was immediately started on a regimen of Chloromycetin, 250 mg. every six hours, erythromycin, 30 mg. every eight hours, and aspirin. A water mattress was to be used for temperature elevation above 39° C. A positive growth of hemolytic *Staphylococcus aureus* was found on throat culture the following day. An admission x-ray of the chest showed infiltration in the midzone of the left lung (Fig. 8A). There was some elevation of the left leaf of the diaphragm. The patient ran a spiking fever with a temperature up to 40° C. during the next three or four days. An x-ray of the chest made six days later revealed spare areas within the left lung, as well as pneumothorax. There was some increased elevation of the left leaf of the diaphragm with mild deviation of the mediastinum to the

Figure 8. Intercostal drainage in staphylococcus empyema (see text for explanation).

right (Fig. 8B). The patient's condition became somewhat improved. However, closed drainage with two intercostal tube drains was instituted which completely expanded the lung with subsequent disappearance of the cavities (pneumatoceles within the lung) (Fig. 8C). The patient's course subsequently was smooth and uneventful. The temperature returned to normal and all evidence of previous involvement within the lung disappeared (Fig. 8D).

Chronic empyema. The most common cause of chronic empyema is inadequate drainage of an acute empyema. This may be due to lack of dependent drainage, inadequate drainage opening or cessation of drainage before closure of the cavity. Lack of dependent drainage is the most common causative factor. Occasionally, chronic empyema occurs as a result of a foreign body in the cavity, such as a sequestrum from an osteolytic rib following rib resection or from drainage material. Drainage of tuberculous empyema has at times been instituted before sufficient information as to the causative organism was secured, thus resulting in chronic empyema.

In chronic pyogenic empyema, a small pleurocutaneous sinus with intermittent drainage of small amounts of exudates is not infrequently present. Likewise, a communication between the empyema cavity and the bronchial tree (bronchopleural fistula) is frequently seen. The clinical features in the chronic form of empyema include a pale undernourished individual showing various degrees of anemia and low-grade leukocytosis. The chest wall on the affected side is shrunk and immobile. Breath sounds over the involved area are absent and the percussion note is dull to flat.

Usually, on the basis of etiologic factors alone, a diagnosis of chronic empyema may be readily suspected. An x-ray examination reveals the area of involvement to be opaque, with or without a fluid level in the cavity. If a bronchopleural fistula or a draining sinus of sufficient size for the admission of air into the space is present, a fluid level will be seen.

After the diagnosis has been established, adequate open drainage, usually by the removal of segments of two ribs in a dependent location, should be made. Improvement in the patient's general condition should also be brought about through the use of transfusions, chemotherapy, vitamins and a nourishing diet. Inspection of the cavity

should be made for the presence of foreign material and the cavity cleaned by irrigation.

Within a period of two or three months, through open drainage alone, the cavity may be reduced considerably in size. In addition, and of even greater importance in the preparation for more adequate surgery, the patient's general condition will be materially improved. In most instances, dependent open drainage in itself will be inadequate for complete obliteration of the cavity. Although, in the past, emphasis has been placed on obliteration of the residual cavity by collapsing the overlying chest wall, at the present time the principle of therapy is based upon mobilization of the empyema wall and surrounding lung, removal of both visceral and parietal portions of the fibrous empyema wall and sufficient reinflation of the underlying lung for obliteration of the pleural space. If the lung tissue adjacent to the area of the empyema is adequately mobilized, the object of the operation will be accomplished. Adequate replacement of blood loss is of paramount importance in this procedure. Closed drainage of the pleural space by use of an intercostal catheter following closure of the chest wall should be rigidly maintained during the postoperative period.

Tuberculous empyema. This condition is almost always secondary to tuberculosis of the lung. Tuberculous empyema is seldom seen at the present time, since the use of pneumothorax therapy for tuberculosis has been largely abandoned, or is not pushed beyond its limitations, and effective chemotherapy has become available for the treatment of pulmonary tuberculosis. In tuberculous empyema, the exudate in the pleural space may vary greatly in density from an extremely thin serous-like material to one fairly purulent in character. In the presence of a bronchopleural fistula, the pleural space may become secondarily infected by pyogenic organisms, in which case the condition is termed "mixed tuberculous empyema." This form of infection carries greater clinical significance and therapy must be based on different principles than in the presence of a pure tuberculous empyema. In the pure infection, symptomatology will vary little from that of the primary condition within the lung. Physical findings are those characteristic of the presence of fluid within the pleural space. In mixed tuberculous empyema, symptomatology will include greater

elevation in temperature and leukocytosis. Likewise, systemic manifestations of a pyogenic infection may be present.

Whereas therapeutic measures for purely tuberculous empyema may vary little from those for the original condition within the lung, therapy for mixed tuberculous empyema will include adequate dependent surgical drainage and chemotherapy for control of the pyogenic organism. If the pulmonary lesion can be adequately controlled, some consideration should be given to an open operation for removal of the localized pulmonary infection by resection, in addition to management of the empyema cavity. Chemotherapy, the use of blood transfusions and attention to the nutritional state of the patient are important aspects of the over-all management of the mixed tuberculous type of infection.

Tumors of the Chest Wall and Pleura. Various tumors of connective tissue origin, such as lipoma, lymphangioma, hemangioma, osteoma and chondroma, may develop in the

chest wall. The most common is chondroma or osteochondroma, which arises from a rib, cartilage or the sternum. Many of these tumors are malignant, especially those of a cartilaginous nature. Because most of them grow toward the pleural cavity, they may reach a considerable size before producing symptoms or before their presence is discovered. The tumor frequently arises at a costochondral junction and, owing to its slow growth, symptoms may be entirely lacking until adjacent structures are affected by pressure. All structures of the chest wall are usually involved by the growth, which is more or less spherical in shape, hard and nodular, with areas of softening due to degeneration. Since metastases are late, the tumor is apt to be considered benign and differentiation is frequently difficult or impossible even on microscopic examination. Of the 213 tumors of the chest wall analyzed by Hedblom, 61.4 per cent were sarcomas. In the absence of metastases, differentiation between the benign and the

Figure 9. Chondroma (see explanation in text).

malignant tumor is impossible before operation. These tumors may also be confused with a dermoid cyst, cold abscess, aneurysm and exostosis.

Figure 9 illustrates the case of a thirty-five-year-old white female who had noted the presence of a tumor of the chest for the preceding seven years. She had experienced fleeting pains beneath the right breast during that time. The tumor had increased slowly during that period, but no symptoms were present on admission to the hospital. Physical findings were normal except for a tumor mass which was firm, nodular and nontender and projected out from the left chest wall for a distance of 2 to 3 cm. over an area from the third to the sixth ribs and from the right border of the sternum to the postaxillary line, being approximately 13 cm. in diameter (Fig. 9A). The tumor was removed through an incision over the fifth right interspace from the sternum to the spine. This also included removal of portions of the fourth, fifth and sixth ribs anterolaterally as well as other elements of the chest wall (Fig. 9B). The breast was elevated during this procedure and was then used to aid in filling the defect. The patient had an uneventful convalescence. An x-ray of the chest following surgery showed only mild reduction in the size of the pleural space on the operated side (Fig. 9C). The tumor mass was spherical in shape, projecting almost entirely into the pleural cavity. It was firm in consistency and quite nodular throughout and measured approximately 14 cm. in diameter. Macroscopic examination showed this to be a chondroma (Fig. 9D).

Treatment consists in wide surgical excision. When the tumor is large, no attempt should be made to preserve the underlying parietal pleura. Positive pressure anesthesia must be used for dealing with the surgical pneumothorax produced. If a large defect in the chest wall remains following removal of the tumor, it can frequently be filled in by the breast or scapula. Plates of Lucite, secured to adjacent ribs or cartilages, have been successfully employed in bridging large defects. Good results may be expected in a benign lesion, but recurrence is the rule following extirpation of a sarcomatous tumor.

A common malignant tumor described by Pancoast arises in the superior pulmonary sulcus. Although the etiologic source has been questioned, it is epithelial in nature and is

now classified as bronchogenic in origin. This tumor gives rise to a characteristic clinical picture of pain in the shoulder, wasting of the muscles of the hand and Horner's syndrome. Roentgenograms reveal a sharply defined opacity in the extreme apex of the pleural cavity, with destruction of one or more of the first three ribs and at times the adjacent vertebrae. X-ray therapy may give symptomatic relief and prolong life in some of the patients. There is no other known effective therapy.

Other malignant tumors frequently seen in the ribs are metastatic carcinoma from the breast and multiple myelomas. The latter are more easily detected here than in other bones.

Tumors of the pleura may be primary or metastatic. The latter are seen much more commonly than the former and are usually secondary to tumors of the breast or lung. A serous or blood-tinged fluid is formed and is usually the first sign of the tumor's presence. Pain of a variable nature is usually experienced. Large quantities of fluid may form, with as much as several hundred cubic centimeters being present and recurring over a period. Examination of the fluid by centrifuging, fixing and staining will usually reveal the presence of malignant cells, especially when the fluid is bloody in character. X-ray examination of the chest will show the presence of fluid and frequently also an eroded rib.

Primary tumors of the pleura include endothelioma, mesothelioma and sarcoma. These are rarely seen and do not present a characteristic clinical picture. Pleural effusion may also accompany these lesions, although it occurs less frequently than in the presence of metastatic tumor. Treatment is by excision if the growth has not extended beyond the limits of surgery.

Diseases and Tumors of the Lungs and Bronchi

By BRIAN BLADES, M.D.,
OWEN GWATHMEY, M.D., and PAUL C. ADKINS, M.D.

BRIAN BLADES, the son of a Kansas doctor, was educated at the University of Kansas and Washington University Medical School. He received his training in thoracic surgery at the hands of Everts Graham and was one of the early disciples who established and extended the principles upon which this specialty rests. Following a distinguished service in thoracic surgery during World War II, he was appointed to the chair of surgery at George Washington University School of Medicine in 1946.

OWEN GWATHMEY is the son of a practicing country physician in King William County, Virginia. Like his father, he was educated in Virginia and graduated from the Medical College of Virginia. He was trained in surgery at George Washington University and is now in practice in Richmond, Virginia.

PAUL CHARLES ADKINS was born in Massachusetts and received his college and medical education at The Johns Hopkins University. He was trained in surgery at The Johns Hopkins Hospital and the hospital of The George Washington University, where he is now Assistant Professor of Surgery.

A thorough knowledge of the anatomy of the trachea and lungs is essential in the evaluation and treatment of pulmonary disease.

The trachea is approximately 11 cm in length. It contains cartilaginous rings for

support, which circumvent the organ except posteriorly. The trachea divides at the carina into the right and left main stem bronchi. The right main stem bronchus angulates slightly at the bifurcation. It gives off bronchi to the right upper lobe, right

middle lobe and right lower lobe. The left main bronchus is longer than the right and has a sharper angulation at the carina. The left upper lobe arises at a greater distance from the carina than its counterpart on the right. The bronchus continues as a left lower lobe bronchus and on both sides the lobar bronchi divide into tertiary bronchi to form the segments of the lung. On the left, the lingula of the left upper lobe arises from the left upper lobe bronchus and is a counterpart of the right middle lobe. The segmental bronchi divide into ramifications forming bronchioles, alveolar ducts and sacs.

The latter contain no cartilage and are, therefore, spongy in nature. Each segment is separate and usually communicates with the adjacent segments, allowing collateral ventilation. This phenomenon is known as air drift. The segments are conical in shape with the apex toward the hilum (Fig. 10).

The main pulmonary artery divides into the right and left pulmonary arteries in the mediastinum. The right pulmonary artery crosses the right main stem bronchus on its anterior aspect and courses downward. It gives off two or three large branches to the apical and the posterior apical segments. It

Figure 10. The bronchopulmonary segments. (From Jackson and Huber.)

descends posteriorly beneath the superior pulmonary vein and gives off a branch to the anterior segment of the upper lobe. This branch lies in the fissure between the superior and middle lobes and gives off two branches to the middle lobe. It continues in the fissure as a lower lobe artery and gives off branches to the corresponding bronchial segments.

The left pulmonary artery arches over the left main stem bronchus to descend in the fissure between the left upper and lower lobes. It has a longer main trunk than the right. It gives off branches to the apical and then to the apical posterior segments as it arches around the main stem bronchus. Continuing in the fissure are two to three segmental branches to the anterior segments. Just below this, one or two branches are given off to the lingular segment of the left upper lobe and the apical segmental artery to the apex of the lower lobe. At this level, the vessel becomes the lower lobe artery and continues as a common trunk for 2 or 3 cm. where it divides into the basilar segmental arteries.

The segmental veins of the right upper lobe and the right middle lobe converge to form the right superior pulmonary vein. The vein crosses in front of the lower lobe artery and enters the left atrium. The inferior pulmonary vein is formed by the segmental veins from the right lower lobe and enters the left atrium with the right superior vein.

The segmental veins of the left upper lobe and lingula form the left superior pulmonary vein which crosses in front of the bronchus just inferior to the left pulmonary artery and enters the left atrium. The left inferior pulmonary vein is formed from the segmental veins of the lower lobe. It courses directly to the mediastinum and enters the left atrium with the other veins.

The bronchial arteries arise from the undersurface of the distal aortic arch. They pass to the anterior surface of the bronchi near the lateral margin. Their distribution is segmental. The bronchial veins drain segmentally and enter the azygos and hemiazygos veins.

The lymphatic drainage of the lungs is divided into superficial and deep plexuses. The superficial ones are just beneath the pleura while the deep accompany the bronchi, pulmonary arteries and pulmonary veins. Both communicate freely and drain into the lymph nodes of the pulmonary hilum and mediastinum. For the most part,

these channels drain superiorly, although they may drain inferiorly toward the abdomen. There are cross-anastomoses from one hilum to the other.

The primary function of the lung is the transfer of oxygen into the arterial blood and the removal of carbon dioxide from the venous blood. This is accomplished by two important pulmonary functions, ventilatory and respiratory.

Ventilatory function is the transport of gases through the respiratory passages to and from the alveoli. Respiratory function is the absorption of oxygen and the elimination of carbon dioxide from the blood stream. These two functions may be altered alone or together by disease processes.

The surgeon should learn in advance the status of the ventilatory and respiratory functions before surgery of the lungs is considered, since decrease in either function may result in a cardiorespiratory cripple after an operation affecting the lung.

The mechanism of normal ventilatory function depends upon certain factors: a mobile and intact thoracic cage, negative intrathoracic pressure, unobstructed larynx and tracheobronchial tree, elasticity of the lung and properly functioning diaphragms. On inspiration, the intrapleural pressures become more negative as a result of expansion of the thoracic cage and descension of the diaphragms. The lungs expand, the bronchi and bronchioles dilate and elongate and air is sucked into the lungs. Upon expiration the reverse occurs and the lungs decrease in size.

Ventilation can be affected by diseases of the larynx and the trachea or bronchi, lung parenchyma, chest wall or diaphragm.

Respiratory function depends upon the permeability of the partition between the alveolar sacs and capillary lumen. Diseases of the lung parenchyma may injure the alveolar capillary membrane and impair oxygen absorption and carbon dioxide elimination. The exchange of gases through the alveolar capillary membrane depends upon the difference in the partial pressures (gradient) of the gases in the alveolar sacs and the arterial and venous capillaries. Normally, the partial pressure of carbon dioxide in the alveoli is between 35 and 45 mm. Hg, whereas, in mixed venous blood, it averages 45 mm. Hg. The partial pressure of oxygen in the alveoli varies from 100 to 120 mm. Hg and in mixed blood it varies from 30 to 40 mm. Hg. Hence, the diffusion of oxygen will be from the alveolar spaces to the blood and

carbon dioxide from the blood into the alveoli spaces. Even though ventilation is normal, parenchymal disease can alter greatly respiratory function, causing an increase of carbon dioxide accumulation in the blood and decrease in oxygen consumption.

Lung volume measurements and determination of oxygen and carbon dioxide transport across the alveolar capillary membrane may be necessary in evaluating patients for resectional surgery. However, in patients who give no history of pulmonary insufficiency, examination of the respiratory rate and pulse rate before and after exercise is a valuable pulmonary function test. The condition of the patient after walking rapidly up a flight of stairs also gives a reliable impression of pulmonary reserve.

The efficiency of the bellows action of the chest and lungs may be obtained from spirometric tracings and from the residual air capacity measurements. The timed vital capacity is of more importance in determining the efficiency of ventilation than is the vital capacity alone. The vital capacity is the volume of air which is collected between maximum inflation and maximum deflation of the lungs. The timed vital capacity is the volume of air which is rapidly exhaled from maximum inflation of the lungs and collected over a three-second period. It should equal the predicted vital capacity. If it is less, pulmonary insufficiency is present and ventilation is impaired.

The maximum breathing capacity (MBC) is the volume of air which is moved in and out of the lungs over a given period, while the patient is breathing as deeply and rapidly as possible. Normal for man is 120 liters per minute, if the maximum breathing capacity is 40 liters or less, then a significant degree of insufficiency is present. Normal measurements of the three-second timed vital capacity and maximum breathing capacity indicate that there is normal lung elasticity, no obstruction of the airways and good movement of the diaphragm.

Residual air studies are helpful in determining the degree of pulmonary insufficiency. Normally, residual air occupies about 25 per cent of the total lung capacity and is the volume of air present in the lung following maximum expiration. A volume of 40 per cent or over indicates pulmonary insufficiency.

Bronchspirometric studies determining the amount of oxygen consumption and ventilation of each lung may be helpful in patients with bilateral disease.

The determination of oxygen and carbon dioxide tension in the arterial blood is important in determining the transport of oxygen and carbon dioxide across the alveolar capillary membrane. These measurements should be obtained both at rest and following exercise. Oxygen consumption, minute ventilation, tidal volume, arterial oxygen saturation, the arterial blood p_{H_2} , the arterial carbon dioxide content and the carbon dioxide combining power are necessary to establish these values.

PULMONARY TUBERCULOSIS

It is important to emphasize that pulmonary tuberculosis is a chronic systemic disease. Surgical treatment, therefore, affects only the predominant manifestation, usually the organ or part of an organ most seriously involved. The discovery and widespread use of the antituberculosis drugs have furnished a method to help control the systemic aspects of tuberculosis, which has not only made earlier and successful operations possible, but has sharply decreased morbidity following all types of surgical intervention.

Early clinical diagnosis of minimal tuberculosis is difficult. The disease may mock the common cold, grippe, influenza and, if severe and fulminating, pneumonia. Physical signs cannot be relied upon to establish the diagnosis but may be suggestive. Rales in the upper lung fields, diminished breath sounds and other physical signs have been described as typical of tuberculosis. Regardless of physical signs, roentgen ray examination of the chest is essential. Emaciation, hemoptysis and other evidences of terminal tuberculosis are now rarely seen as presenting signs and symptoms.

The nationwide availability of chest x-ray surveys has resulted in the detection of many early cases of tuberculosis. Everyone, young and old, should have a roentgenogram of the chest made at least once a year, not only for tuberculosis detection but for the detection of other diseases of the lungs.

The final and absolute diagnosis of pulmonary tuberculosis cannot be made until tubercle bacilli are found in the sputum. A single positive sputum examination is not reliable and must be duplicated and, preferably, confirmed by culture. Failure to observe these precautions has resulted in the hospitalization of patients for long periods with an erroneous diagnosis of tuberculosis. Until effectual chemotherapeutic agents were available in the treatment of tuberculosis, surgical therapy was largely confined

Figure 11 A, Roentgenogram of chest showing destruction of the left lung. There was stenosis of the left main bronchus. B, Appearance of the chest following pneumonectomy. Many surgeons would perform a thoracoplasty at the time of pneumonectomy or later to prevent overdistention of the remaining lung.

to operations designed to collapse or partially collapse the diseased lung to put the organ at rest. If bed rest did not result in healing of the lesion, artificial pneumothorax sometimes combined with internal pneumonolysis, phrenic nerve paralysis, pneumoperitoneum and, finally, collapse of the chest wall by thoracoplasty were accepted procedures.

A great variety of operations have been suggested for tuberculosis: division of the scalene muscles to relax the apex of the lung, extrapleural pneumonolysis, cavity drainage, oleothorax, paraffin plombage and extrapleural pneumothorax. Except under unusual circumstances, these operations are obsolete.

Tuberculosis is a multiform disease and there has always been some disagreement, even among the most skilled, in the management of each specific problem. Even with the most recent advances each case requires individualization in the decision for the exact type of surgical approach and the timing of the operation.

Artificial Pneumothorax. Collapse of the lung by introduction of air into the pleural cavity is now rarely undertaken but was a very popular method of treatment in the past. Although the procedure is easily performed, the complications of artificial pneumothorax may be serious, including development of serous fluid, empyema, bronchopleural fistula or an obliterative pleuritis

with associated loss of pulmonary function. The practice of always attempting artificial pneumothorax before recommending more radical surgical treatment has been discontinued.

Pneumoperitoneum. Elevation of the diaphragms by the introduction of air into the peritoneal cavity has been more popular in the past decade. The principal use for the procedure is in those patients who do not respond to chemotherapy alone or whose condition is too serious for major surgical intervention. There are sharp differences of opinion concerning the value of pneumoperitoneum, but many believe the incidence of sputum conversion and cavity closure with combined use of chemotherapy and pneumoperitoneum is significant. Contraindications include chronic fibroid disease with thick-walled cavities, caseous foci and endobronchial tuberculosis. A history of abdominal disease with subsequent operation is a positive contraindication to the introduction of air into the peritoneal cavity.

Thoracoplasty. Thoracoplasty was reserved until other operations had failed in the early days of the surgical treatment of tuberculosis. Later, cases were selected on the basis of extent and location of disease and permanent collapse of the diseased lung tissue became a popular and valuable operation. With the increasing popularity of pulmonary resection for tuberculosis, however, the number of thoracoplasties performed is

diminishing. The undesirable features include leaving diseased tissues in the body and depending upon relaxation and collapse to cause permanent healing. Moreover, thoracoplasty may cause varying degrees of deformity. It appears from early results that excision of the diseased lung tissue, combined with chemotherapy, will give better results than collapse therapy. At the present time, the principal value of thoracoplasty, usually a limited one, is to decrease the size of the pleural space after the removal of a lobe or a lung. This procedure will help prevent overdistention of the remaining lung tissue and will decrease the incidence of bronchopleural fistula. Depending upon the patient's condition and the circumstances of the case, the thoracoplasty can be performed at the time of the lobectomy or pneumonectomy, or may be delayed until a later date. Some surgeons believe that thoracoplasty is particularly important following pneumonectomy to prevent overexpansion and shift of the remaining lung, which in turn might result in reactivation of tuberculous foci in the apparently sound lung.

Pulmonary Resections for Pulmonary Tuberculosis. The majority of patients with predominantly unilateral disease, in whom response to chemotherapy and bed rest is not satisfactory, are now treated by removal of the diseased portion of the lung. Depending

upon the extent of the disease, the operation may be pneumonectomy (Fig. 11), lobectomy (Fig. 12), segmental resection of a lobe (Fig. 13) or, in some instances, a simple wedge resection of the involved tissues. This approach to the surgical treatment of pulmonary tuberculosis has been made possible by the discovery and use of the chemotherapeutic agents effective against the disease. Moreover, during the past two decades, there have been perfections of techniques for pulmonary resection, methods for the evaluation of pulmonary function and tremendous advances in anesthesia. The concept of removing the diseased lung tissue in patients having pulmonary tuberculosis is more than a half-century old but could not be accomplished with safety until rather recently.

The present tendency is to recommend removal of tuberculous foci much earlier than would have been acceptable a few years ago. The work of Medlar and his associates has strongly influenced this trend. They contend that necrotic, caseous tuberculous foci are important in instances of clinical recurrence after apparent arrest. They caution against operations if tubercle bacilli can be found in the sputum and depend upon the antituberculosis drugs to control this factor. And finally, they justify operations on small lesions to conserve func-

Figure 12. A, Roentgen ray appearance of disease of the right upper lobe B, Postoperative roentgenogram after upper lobe lobectomy and limited thoracoplasty.

Figure 13. A, Minimal lesion located in the right upper lobe. B, Postoperative x-ray appearance of the lung after removal of the posterior and apical segments of the right upper lobe.

tion of the lung tissue and point out that the most dangerous pulmonary disease is located in the superior and posterior portions of the pulmonary lobes. Modern surgeons, therefore, rely upon the antituberculosis drugs to control the systemic phase of the disease and often excise the predominant, demonstrable foci as delineated on the x-ray film. Opportunities to operate upon earlier lesions have been made possible by the widespread use of x-ray surveys for the detection of the disease.

The first infection of the lung by the tubercle bacilli usually is followed by rapid healing and the formation of a Ghon's complex. If the host's resistance to tuberculosis is low, there may be a rapid spread with caseation and exudation with little fibrosis. Scarring and fibrous encapsulation may come later as resistance increases. There is usually marked enlargement of the hilar lymph nodes associated with the initial pulmonary lesion if it is progressive.

Reinfection tuberculosis is the type which usually is of interest to the surgeon. These lesions are characterized by marked fibrous reaction and little tendency to further involve local lymph nodes. The degree and seriousness of reinfection tuberculosis depend principally on the host's resistance. The late manifestations of reinfection are scars, usually in the upper lobe and often in the apical or posterior segments of the up-

per lobe. These lesions may or may not be associated with caseation. The mechanism which accounts for localization in the posterior portions of the upper lobes is not understood.

The allergic reaction to the tubercle bacilli has some bearing on the types of disease. Caseation and abundant exudation may be present if the allergic factor is predominant. In instances where encapsulation of the disease is extreme, a small, round focus may present and produce the formation of a tuberculoma. If liquidation and necrosis continue, there will be cavity formation with communications with one or more bronchi. In patients with good resistance, the surrounding fibrous connective tissue will be laid down in an effort to check the disease. These lesions are often termed "fibrocaceous tuberculosis." Surgical extirpation combined with antibiotic therapy is usually required to obtain a satisfactory result when the disease has reached this stage.

The diversiform nature of tuberculosis results in a wide variety of pathologic lesions. Moreover, there are sharp differences of opinion concerning the mechanisms involved.

There is practically complete agreement that if a thoracoplasty has failed to arrest the disease, pulmonary resection will be necessary. The presence of tuberculous bronchostenosis or bronchiectasis constitutes an

other positive indication for excisional surgery, as do instances of extensive lung destruction. In patients who have had thoracoplasty without conversion of sputum, lobectomy or pneumonectomy will be necessary. Giant cavities and lower lobe disease are also considered indications for extirpation of the involved lobe or lobes.

The presence of a suspected tuberculoma (Fig. 14) usually demands excision of the involved tissue. The most important reason for excision of this lesion is to differentiate it from a bronchogenic carcinoma, since the roentgen ray appearance may be identical and, secondly, tuberculomas of any size may undergo cavitation and result in active disease.

Chemotherapy. The discovery of streptomycin by Schatz and Waksman, in 1944, was followed by Hinshaw's demonstration, in 1945, that the drug was effective in clinical tuberculosis. After a trial-and-error period, it was found that the combination of para-aminosalicylic acid (PAS) and streptomycin reduced the hazard of bacterial resistance to streptomycin used alone. Both in medical treatment and in preparation for any type of surgery, chemotherapy is uniformly employed. In addition, following operation, drug therapy is of utmost importance to prevent spread of disease and to aid in healing, particularly of the divided bronchus. Drug therapy is continued after operation as protection against late complications or reac-

tivation of disease. The length of time the antituberculosis agents are employed depends upon the needs of each individual patient.

The isonicotinic acid derivatives, particularly isoniazid or isonicotinic acid hydrazide introduced a few years ago, are now used in combination with both streptomycin and PAS, depending upon the strains of tubercle bacilli resistance to the various drugs. New antimicrobial agents are constantly being discovered and the exact pattern of drug therapy will probably change as time goes on.

LUNG ABSCESS

A lung abscess is a circumscribed collection of pus within the pulmonary parenchyma. Pulmonary gangrene is a massive destruction of lung tissue exceeding that commonly seen with the ordinary lung abscess. These conditions, therefore, are similar, only varying in extent. The widespread use of the various antibiotics has made lung abscess a rare disease.

Single or multiple lung abscesses can result from a variety of causes. Probably the most common is aspiration of infected material during operations on the upper respiratory passages, the mouth and nose. Unconsciousness for any reason increases the chance of aspiration of foreign material. Infected emboli in the blood stream may lodge in the lung and result in abscess formation. Extension of bronchiectasis into the lung parenchyma or infections distal to obstructing carcinomas may produce the condition.

Figure 14. A tuberculoma demonstrated by x-ray film. The differential diagnosis between bronchogenic carcinoma and tuberculosis could not be made until the tissue was excised.

Figure 15. A large lung abscess caused by bronchogenic carcinoma. This possibility must always be considered, particularly in older patients.

The diversiform nature of tuberculosis results in a wide variety of pathologic lesions. Moreover, there are sharp differences of opinion concerning the mechanisms involved.

There is practically complete agreement that if a thoracoplasty has failed to arrest the disease, pulmonary resection will be necessary. The presence of tuberculous bronchostenosis or bronchiectasis constitutes an-

Figure 16. Roentgenograms showing the appearance of an atelectatic middle lobe typical of a middle lobe syndrome

diseased lobe. At operation enlarged, firm lymph nodes are present which compress the proximal portion of the middle lobe bronchus. This is particularly striking on the inferior surface of the bronchus.

The middle lobe is atelectatic with varying degrees of fibrosis and associated bronchiectasis and multiple small abscesses.

The same clinical and roentgenologic findings may result from occlusion of the bronchus by bronchogenic carcinoma. This possibility must always be considered in cases of the middle lobe syndrome.

CHRONIC SUPPURATIVE PNEUMONITIS

The definite etiologic agent for chronic suppurative pneumonitis is unknown. The condition also has been referred to as non-putrid pulmonary suppuration and chronic sclerosing pneumonitis.

This nonspecific disease produces signs, symptoms and pathologic changes which are fairly consistent and justify its description as a separate disease entity.

The onset is usually insidious without a history of an acute respiratory illness. The most common symptoms are chronic cough, chest pain and, later, hemoptysis. Symptoms are usually of weeks' or months' duration with gradual increase in severity. There is usually little or no weight loss. Fever, if present, is low grade.

The physical findings are vague with some increased dullness over the involved lung and frequently coarse rales.

X-rays of the chest will show diffuse infiltration and sometimes atelectasis. Bronchoscopic examination will usually reveal in-

Figure 17. The roentgenographic appearance of chronic suppurative pneumonitis. An identical roentgenogram may be seen in cases of bronchogenic carcinoma.

In a patient in the older age group with a lung abscess, the possibility of a carcinoma should always be considered seriously (Fig. 15). Trauma is a possible, but unusual, etiologic factor.

Pyogenic organisms of any type may be found in lung abscesses, including streptococci, pneumococci, staphylococci and fusiform bacilli. If the pus in the abscess is foul smelling, both aerobic and anaerobic organisms are often present. The putrid lung abscess, common before antibiotics were available, is now a rare lesion. Apparently, the general use of chemotherapy destroys some of the bacteria and, particularly, the symbiosis between anaerobic and aerobic organisms which produces the necrotizing, foul-smelling infections.

Before penicillin, streptomycin and the more recently discovered antibiotics were available, lung abscesses constituted a very serious disease and fulminating pulmonary gangrene was usually fatal.

If the abscess did not empty spontaneously by coughing, or sometimes with the aid of bronchoscopy, drainage operations were necessary. The operation was dangerous and the convalescence long. If the abscess became chronic, the prognosis was even more serious.

In the formative stage, before liquefaction of the lung tissue has produced a visible cavity or copious amounts of foul-smelling sputum, it is impossible to make a differential diagnosis between pulmonary abscess and pneumonia, consequently, almost all patients receive antibiotic therapy immediately. It is most likely that a certain number of persons with lung abscess recover from a pulmonary infection without the lesion progressing to abscess formation or the diagnosis becoming apparent. Most lung abscesses can be aborted by antibiotic therapy unless a cavity develops. Even under these circumstances, postural drainage, bronchoscopic aspiration and antibiotic therapy may cause healing of the lesion. Even if the abscess does heal promptly, visualization of the bronchial tree with Lipiodol at a later date may show residual bronchiectasis.

If the lung abscess does not respond to conservative therapy, most surgeons now prefer to excise the lesion rather than to drain it, since the incidence of residual bronchiectasis after drainage of lung abscesses is high. The amount of lung tissue removed will depend upon the extent and location of the abscess. Occasionally, in de-

bilitated and poor-risk patients, external drainage is safer. This must be done through an adherent pleura and it is often necessary to excise the lobe involved at a later date to obtain an entirely satisfactory result.

FRIEDLANDER'S PNEUMONIA

Pulmonary infections caused by Friedlander's bacillus (*pneumobacillus*, *Bacillus mucosus capsulatus*, or *Klebsiella pneumoniae*) may produce pneumonic consolidation which is usually lobar in type, associated with multiple abscesses and minute necrotic foci. As the disease progresses, the necrotic foci may liquefy and form large cavities. If the lesions become chronic, organization and fibrosis of the diseased tissue produce a dense, heavy granulation tissue.

If the disease does not respond to medical therapy, usually with Achromycin, streptomycin or other antibiotics, depending upon sensitivity studies of the bacteria, extirpation of the involved lung parenchyma should be recommended. In Friedländer's bacilli infections this usually involves lobectomy and, since these infections do not follow segmental boundaries, removal of the entire lobe or lobes involved is necessary. Antibiotic therapy must be continued during and after the operation. The prognosis in persistent cases of Friedlander's bacillus disease of the lung is poor, because even after operation the disease may appear in the same or contralateral lung.

MIDDLE LOBE SYNDROME

The right middle lobe is particularly vulnerable to atelectasis with associated suppurative changes. This probably results from compression of the middle lobe bronchus by lobar lymph nodes. The middle lobe bronchus is at the apex of the lymphatic channels to both the upper and lower lobes and is, therefore, particularly subject to impingement of lymphadenopathy.

The symptoms are commonly chronic cough with or without productive sputum, recurrent attacks of pneumonitis with fever, and hemoptysis. Any or all of the symptoms may be present.

Physical signs of consolidation of the middle lobe are usually present. X-rays will show atelectasis of the middle lobe and if bronchograms are made a block of the middle lobe bronchus is usually demonstrated. On bronchoscopy the middle lobe bronchus is markedly stenotic with associated edema and inflammation (Fig. 16).

The proper treatment is extirpation of the

have had heavy sedation and depression of respiration. Pain alone may restrict portions of the chest wall with resulting accumulations of viscid material. Endobronchial tumors, aspirated foreign bodies and bronchial stenosis have the same effects (Fig. 19).

Prevention consists of careful nursing care, frequent change of position and encouraging the patient to cough and breathe deeply, particularly after having a general anesthetic. If atelectasis should develop, it should be relieved at once either by coughing or by endotracheal aspiration with a catheter or by bronchoscopy, if necessary. Chemotherapeutic agents should be employed prophylactically to prevent residual infections even after the collapse has been relieved.

CONGENITAL ANOMALIES OF THE LUNG

Occasionally there may be congenital absence of an entire lung. More frequently, however, one lung has remained in a fetal state and never expanded. Tremendous variations may be found in the locations of interlobar fissures and not infrequently in the number of lobes in the lung. A fairly common and sometimes troublesome anomaly is an aberrant bronchial artery rising directly from the aorta and entering the lung. These vessels may be large and, if injured during an operative procedure, may cause serious hemorrhage. If a pulmonary lobe or lung has remained in the fetal state, it should be removed because, in most instances, infection, bronchiectasis and hemorrhage will occur as the patient's age progresses.

Another common congenital anomaly is the accessory lobe of Wrisberg, or azygos lobe. Its chief importance is that it may be confused with other conditions when detected on a roentgenogram of the chest. An azygos lobe is found in less than 1 per cent of persons having x-ray examination.

True congenital cysts of the lung are relatively rare and in the past have been confused with emphysematous blebs or bullae. They are very similar or identical with bronchogenic cysts which may occur in the mediastinum. They may be thin walled, containing clear fluid, or a mixture of solid type of lesion with some fluid. These cysts have the characteristic epithelial lining found in the remainder of the respiratory passages. Pressure on adjacent thoracic structures may cause symptoms. Eventually the cysts become infected and therefore should be removed. Hemoptysis is a rela-

Figure 20. A huge emphysematous bleb displacing the mediastinum to the right. Both on roentgen ray examination and clinically, confusion with tension pneumothorax is easy. Removal of the bleb resulted in re-expansion of the left lung.

tively rare complication. The proper treatment is surgical extirpation.

There has been some confusion in the terminology concerning cystic bronchiectasis and congenital cystic disease. If the cysts are multiple, bronchograms may give the impression of cystic bronchiectasis. More often, however, the cyst cannot be filled with the radiopaque medium.

Emphysematous blebs and bullae are much more common than true congenital cysts. These lesions are commonly found in patients with pulmonary emphysema and asthma. The exact mechanism in the formation of these lesions is not understood. Loss of elasticity of lung tissue is certainly a prime factor and, particularly in patients with asthma, plugging of the bronchioles with mucus may cause dilatation distal to the obstruction. This situation might occur after any inflammatory disease of the lung.

With the development of giant air cysts, surgical intervention may be necessary. The cysts may be so huge that collapse of adjacent lung tissue will have serious effects on cardiorespiratory function (Fig. 20). In extreme cases, pneumatocele may occupy the entire hemithorax and produce the so-called vanishing lung phenomenon. Under these circumstances, the communication to the air cyst through the bronchus is usually of

flammatory changes in the bronchus to the affected part of the lung and varying amounts of purulent drainage (Fig. 17).

Chronic suppurative pneumonitis usually occurs in the older age group and it is often impossible to differentiate from bronchogenic carcinoma. This is even true when the lung is exposed at operation. The grossly involved lung tissue is in most cases infiltrated and atelectatic. Hard nodules may be present and also small zones of necrotic tissue. Final differentiation may depend upon microscopic sections.

In chronic suppurative pneumonitis there is extensive interlobar fibrosis and thickening of the alveolar walls. There is often considerable lymphoid and plasma cell hyperplasia.

The proper treatment is excision of the diseased lung tissue and a more radical operation if the lesion proves to be secondary to a tumor.

Attenuation of acute pneumonia or other suppurative disease of the lungs by antibiotic therapy may play a role in the production of a slowly progressive chronic lesion.

STAPHYLOCOCCAL PNEUMONIA

Infections with virulent antibiotic-resistant staphylococcus appear to be increasing. Involvement of the lungs with staphylococcal

Figure 18. The roentgenographic appearance of an unresolved staphylococcal pneumonia. The acute phase of the pneumonia was controlled by antibiotics, but the right lower lobe was irreparably damaged. It was necessary to perform a right lower lobe lobectomy before the disease could be cured.

pneumonia may produce conditions which require surgical intervention.

The most common complication is empyema. With or without associated empyema, however, there may be serious damage to the lung parenchyma with consolidation and multiple small abscess formation. The abscesses may become confluent and develop cystlike lesions or pneumatoceles. This is particularly true in children. Excision of the irreparably damaged lung tissue may be necessary after the acute pneumonia has subsided (Fig. 18).

BRONCHOLITHIASIS

Broncholiths or lung stones, which usually result from the erosion of a calcified lymph node into the bronchus, may cause bronchial obstruction. Infection distal to the obstruction, if not relieved, may destroy the affected portion of the lung. Excision of the diseased lung tissue may be necessary. Broncholithiasis is often associated with severe hemoptysis which will require surgical intervention.

ATELECTASIS

Atelectasis, or imperfect expansion of the lung, may be the result of a variety of mechanisms. The entire lung, a lobe or a segment of the lung may be involved. The most common cause for this condition is the blocking of a bronchus or bronchiole with viscid mucus. The spontaneous removal by coughing, or by endotracheal aspirations, will result in rapid re-expansion of the involved zone. The condition is common following operations, especially in patients who

Figure 19. Atelectasis of the right lower lobe as shown by roentgen ray examination.

may not establish either the presence or the extent of bronchiectasis. Precise diagnosis and localization depend upon delineation of the tracheobronchial tree with a radiopaque medium.

It is also important to note that, after any inflammatory process, bronchograms may show some cylindrical dilatation of the bronchi. As the inflammation subsides, the bronchi may return to normal. If radiopaque studies are made soon after pneumonia of

any type, a false impression of bronchiectasis may be obtained. This has been termed pseudo or reversible bronchiectasis. Delay of three or four weeks in preparing bronchograms after an acute infection will prevent this error in diagnosis.

Bronchiectasis is most commonly confined to the basal segment of one of the lower lobes, associated with disease of the right middle lobe or the lingula of the left upper lobe (Fig. 21). Except in patients in whom

Fig. 21

Fig. 22

Figure 22. Bronchiectasis of the right upper and middle lobes. Location of the disease in the upper lobes suggests a tuberculous origin.

Figure 23. Bilateral bronchiectasis involving both lower lobes, the right middle lobe and lingula of the left upper lobe. In young patients in good general condition, bilateral lobectomy is feasible. In the older age group, conservative management is usually preferable.

Fig. 23

the ball-valve type with air entering the cavity but not escaping in sufficient quantity. In addition to the mechanical factors, therefore, there is created an unusually large dead air space which will dilute tidal air requirements. In instances of single large, giant bullae, excision of the lesions is usually followed by gratifying improvement.

Single or multiple bullae on the surface of the lung may occur in otherwise healthy young people and rupture of one or more of the lesions produces a sudden and sometimes severe pneumothorax. Interstitial rupture of a bleb with dissection of the air along the line of cleavage of the bronchi and blood vessels may produce mediastinal emphysema with progression to the neck and face. These lesions may be unilateral or bilateral. Spontaneous pneumothorax may occur on one side or both.

In a patient with a small pneumothorax without severe symptoms, aspiration with a needle may result in re-expansion of the lung and formation of pleural adhesions with no further difficulty. If, at the time of the first pneumothorax, aspiration fails to control the intrapleural pressures and a leak continues, catheter drainage with water seal may be necessary as an emergency measure. Most patients with this severe condition will require surgical intervention. If two or more episodes of spontaneous pneumothorax have occurred, surgical treatment should be recommended.

In the past, various sclerosing agents have been injected into the pleura to produce adhesions and prevent further leaks, either through the thoracoscope or with needle and syringe. Modern treatment of spontaneous pneumothorax, however, consists of thoracotomy, excision of visible blebs and sterile talc poudrage of the pleura to promote strong adhesions. Water seal drainages should be maintained after the operation until the lung is completely re-expanded. Before operation is performed upon patients for spontaneous pneumothorax, the possibility of tuberculosis must be considered and ruled out.

BRONCHIECTASIS

The term "bronchiectasis" means dilatation and thickening of the wall of the bronchi or bronchioles. Almost always a chronic inflammation will occur in the dilated bronchioles, which becomes permanent in nature. As the disease progresses, there is thickening of the walls of the bronchi and bronchioles and a loss of elasticity. Accumu-

lations of infected material lead to a cough productive of thick sputum in the untreated patient.

Occasionally, the first manifestations of the lesion will be bleeding from erosion in the walls of the affected portion of the lung. Hemoptysis from bronchiectasis may be severe and not infrequently results from erosion of a bronchial artery which is enlarged as a consequence of inflammatory changes accompanying the disease.

Usually two types of the disease are considered—congenital and acquired.

The congenital type is extremely rare. When it does occur, it is due to developmental defects of a lobe or lung which become infected and produce the clinical manifestations of bronchiectasis, usually at an early age. There is considerable controversy on the precise differentiation of cystic disease of the lung and congenital bronchiectasis.

The acquired variety is much more common and usually follows pneumonia, whooping cough, measles or inflammations of the lung from any cause. A persistent atelectasis may produce residual bronchiectasis. Obstruction of the bronchi by foreign bodies or tumors may result in bronchiectasis distal to the obstruction. The reduction in the incidence of cases of bronchiectasis, since antibiotics are available, indicates clearly the predominance of the acquired type of disease.

The classical picture of bronchiectasis, including chronic cough, foul-smelling sputum and, in the late stages, hemoptysis and clubbing of the fingers, is now rarely encountered. The patient is more apt to complain of easy fatigue and some chronic cough, which usually is not strikingly productive. These changes in the clinical appearances result from the frequent and early use of antibiotics. There is a history of frequent colds, gripe or pneumonia-like attacks and sometimes associated nasal sinusitis. Bronchiectasis is an insidious, slowly progressive disease and the patient may not be aware how handicapped he is until the condition is relieved. Pleurisy pain is a common and often ignored early indication of disease in patients with little cough and sputum. In the far-advanced stages, there are fever, chills and progressive emaciation.

Physical signs may be absent or consist of impaired resonance, distant breath sounds or extensive coarse, bubbling rales.

It is important to emphasize the fact that the conventional roentgenogram of the chest

Figure 24. Echinococcus cysts involving the left lower lobe. The wall of the cyst in the superior division of the lobe has been removed and the fibrous tissue reaction of the bed is apparent. The second intact cyst is seen in the basilar division.

lobectomy and segmental resection constitute desirable methods of treatment. Care should be taken during operation to remove the cyst intact to prevent spillage and anaphylactic reactions.

FUNGUS INFECTIONS

Histoplasmosis. Asymptomatic histoplasmosis may cause granulomatous deposits in lung tissue. Differentiation from early bronchogenic carcinoma and tuberculoma may be difficult. Positive reactions to skin tests and complement fixation tests, however, may be helpful. Some authors believe that tuberculous lesions in the form of so-called tuberculomas have been confused with histoplasmosis even after the lesions have been excised.

Blastomycosis. Blastomycosis may occur in the lung, but it is rare and usually the skin manifestations and other stigmata of the disease are more prominent.

Coccidioidomycosis. Coccidioidal granuloma resulting from infection with *Coccidioides immitis* appears commonly in endemic areas in California, Texas and Arizona. More recently, transmission has occurred from dust in airplanes and the disease should be considered even if the patient has not been in the endemic area. Early manifestations include symptoms of bronchopneumonia with chills and fever. Residual lesions may occur in the lungs and cavitate. Probably the only positive indication for surgical intervention with excision of the

lesion is hemoptysis caused from the cavitation.

Pulmonary Actinomycosis. Actinomycosis of the lung may be confused with ordinary pyogenic infections or with bronchogenic carcinoma. When the infection does occur, the tissues become edematous and fixed. Pus which is found within the lesion will often have the characteristic sulfur granules suggesting the diagnosis.

The onset of the disease may be insidious and mock lung cancer or pulmonary tuberculosis. Pain is usually absent. The positive diagnosis can only be made when the causative organism is located in the tissue or the pus.

Before chemotherapeutic agents were available, the prognosis of the patient having pulmonary actinomycosis was extremely poor. Multiple incisions and drainages of abscesses of the lung often resulted in chronic draining sinuses and eventually metastasis of the disease to the brain, liver or elsewhere, with fatal termination. Modern treatment consists of excision of the diseased lung tissue combined with drug treatment, usually consisting of sulfadiazine and penicillin.

LIPOID GRANULOMA

Lipoid granuloma of the lung may result from inhalation of various oils, usually employed in nasal sprays or from aspiration of mineral oil.

The disease is usually bilateral and is most

scarring of tuberculosis has caused bronchiectasis, the disease is uncommon in the upper lobes (Fig. 22). Bilateral bronchiectasis (Fig. 23) is present in 40 to 50 per cent of the subjects.

The type of dilatation, as visualized by radiopaque studies, may be cylindrical, fusiform or saccular. Symptoms are apt to be more severe with the saccular type, but there is not complete correlation between x-ray appearance and the severity of the disease.

Unless the patient's general condition or the extent of the disease precludes excision of the diseased lung tissue, surgical intervention should be undertaken. The choice of lobectomy, segmental resection or pneumonectomy is made after visualization of the dilated bronchi with bronchograms and exact localization of the disease. A three-dimensional concept of the bronchi is essential for identification of the various lobes and segments. Both frontal and oblique projections on roentgen ray examination are necessary.

Inhalation therapy with a bronchodilator, combined with one of the detergents, and antibiotic therapy are useful in preoperative preparation. Postural drainage combined with bronchoscopic aspiration may be necessary in advanced cases. In patients with extensive disease precluding surgical treatment, these measures are helpful in controlling the infection.

The modern operations of lobectomy, pneumonectomy and segmental resection have been sufficiently perfected so that both mortality and morbidity are very low. Even in instances of bilateral disease, successful operations are not uncommon. Both lower lobes, the right middle lobe and the lingula of the left upper lobe have been removed successfully.

The antibiotics, particularly penicillin, have played an important role in reducing both mortality and morbidity. Patients with severe infection can be practically freed of purulent secretions and cough before operation and protected during the postoperative period.

ECHINOCOCCUS CYST

Pulmonary echinococcus cysts, or hydatid cysts, may be present in the lung as a result of invasion of the tapeworm, *Echinococcus granulosus*.

Echinococcus disease is rare in the United States but is common in other parts of the world, particularly in South America, Italy,

Australia and New Zealand. Increase in world-wide travel incident to two world wars has made the disease more common.

The adult stage of the disease is found in the dog (definite host) which transmits the ova in the feces. The ova may then be ingested by intermediate hosts, either animals or human beings. The outer coat of the ova is digested in the stomach and the embryo burrows through the mucosa, passing into the portal blood stream, and usually lodges in the liver, in about 10 per cent of the subjects there is transmission to the lung.

The developing embryo expands to form a cyst with two layers. The internal wall usually contains the active parasites. Daughter cysts may be formed from the germinal layer or from the developing blood capsules. In pulmonary echinococcus cysts, compression of the lung causes a layer of fibrous material to form about the cysts (Fig. 24). These lesions grow slowly but steadily and may reach enormous sizes. Serious complications include erosion of the cyst into a bronchus or into the pleural cavity.

Echinococcus cysts of the lung are usually asymptomatic unless complications occur or until a cyst attains enormous size. Travel at high altitudes in an airplane may cause expansion of a cyst, producing symptoms which have not been noted before.

Chronic cough, mild chest pain and dyspnea may result from pressure. Rupture of the cyst into a bronchus may be followed by hemoptysis or the sudden expectoration of large amounts of clear fluid.

Anaphylaxis may be dangerous if absorption of the hydatid antigen occurs in a patient who has already been sensitized to the development of the cyst. Anaphylactic reactions are characterized by vomiting, diarrhea, a skin rash and asthmatic-like attacks. In patients having extreme cases, cyanosis, tachycardia and even delirium and coma may be noted.

Physical signs are variable and not dependable. Cysts are easily visualized in roentgenograms and are spherical or ovoid, discrete and homogeneous.

The history of exposure or possible exposure, combined with roentgen ray findings, may suggest the true condition and confirmation can usually be made by the high eosinophilic count and positive reactions to the Casoni intradermal test, complement fixation and precipitin test.

In the past, symptomatic echinococcus cysts of the lung were marsupialized, but, since the perfection of their techniques,

States 20 per cent of cancer deaths among males between the ages of forty and seventy years. In 1955, there were 27,000 recorded deaths from bronchogenic carcinoma.

Carcinoma of the lung is primarily a disease of older age. There is little doubt that the increase in life expectancy plays a role in the increased incidence of the disease. Nevertheless, isolated cases have been reported in young adults and even in children.

Studies by the United States Public Health Service and others indicate that there is an actual increase in the frequency of bronchogenic carcinoma. Some of the increase, however, may be more apparent than real since there is greater knowledge and interest in the problem.

The increase in the frequency of pulmonary cancer appears to be uniform throughout the world. There is, however, a relationship between the prevalence of this tumor and the diagnostic facilities available. In locations where facilities for chest x-rays, bronchoscopy and thoracotomy are sparse, the number of deaths ascribed to lung cancer has remained relatively low. Almost invariably, however, when these facilities become available the incidence of bronchogenic carcinoma rises.

Etiology. Voluminous, ominous and controversial reports on the etiology of bronchogenic carcinoma featured in newspapers and magazines have frightened and bewildered the public. Moreover, there are sharp differences of opinion among experts in the medical profession concerning this question.

A considerable portion of these reports has been concerned with the relationship of cigarette smoking and lung cancer. On the basis of studies in the United States and in England, there appears to be a statistical relationship between the use of cigarettes and the frequency of bronchogenic carcinoma. In addition, the production of skin cancer in mice by tobacco tars by Graham and Wynder has added support to the theory of a cause-and-effect relationship between tobacco and cancer. Nevertheless, there is still room for doubt concerning a direct relationship between cigarette smoking and malignant disease. Other surveys have shown that a statistical affinity can be demonstrated between bronchogenic carcinoma and environmental factors such as air pollution and smoke.

It appears that the effects of radioactive ore may be a valid factor in the development of malignant lung tumors. Approximately 50 per cent of the deaths among

workers in the cobalt mines of Schneeberg and Joachimsthal were due to lung cancer.

Symptoms. The location of a malignant tumor in the bronchopulmonary tree is extremely variable and may occur in the main stem bronchus or originate peripherally in a terminal bronchiole. The presence or absence of early symptoms is usually dependent upon the location of the tumor. A centrally located tumor may cause bronchial obstruction with the accompanying symptoms. Conversely, a peripheral tumor may remain asymptomatic until an advanced stage. Symptoms associated with peripheral lesions usually result from involvement of adjacent structures and the tumor is frequently inoperable when such symptoms appear. The most common symptoms of bronchogenic carcinoma are cough, hemoptysis, chest pain, dyspnea and fever.

Cough. Cough is the most common presenting symptom of bronchogenic carcinoma. The cough is usually the result of stimulation of the cough mechanism by the tumor or the cellular debris of a tumor. The alert physician should consider the possibility of a malignant tumor in any adult patient with a persistent cough or in a patient who does not respond to the usual antitussive medications. Many persons who smoke have a dry "smoker's" cough. Any change in the character of the cough bears investigation. A cough accompanied by wheezing, especially of a unilateral nature, may be indicative of partial bronchial obstruction due to neoplasm.

Hemoptysis. Hemoptysis is not a common initial symptom in patients with bronchogenic carcinoma. Ariel and co-workers report an incidence of 5.6 per cent in an analysis of 1109 cases. In far advanced cases hemoptysis is more common.

Every patient with hemoptysis should be thoroughly investigated. Necessary diagnostic studies include roentgenograms of the chest, bronchoscopy and bronchography.

Pain. Chest pain associated with bronchogenic carcinoma may be due to involvement of the parietal pleura and chest wall by tumor. In more advanced lesions intercostal nerve pain is characteristic. Some patients complain of vague discomfort or feeling of fullness in the chest on the side of the tumor. The exact etiology of this sensation is unknown, but it is not necessarily a sign of chest wall involvement or inoperability.

Dyspnea. Shortness of breath associated with a bronchogenic carcinoma is usually of grave significance. The dyspnea may be

frequently located in the lower lobes because the oil gravitates to those organs. The right lower lobe is often more involved than the left. The lesions are firm and may be either diffuse or nodular.

Infants and older people are particularly vulnerable to the aspiration of foreign material. Accordingly, lipoid granulomas are more apt to be encountered in individuals of these age groups.

Many patients with lipoid granulomas of the lung have no symptoms. If symptoms are present, they usually consist of cough, sometimes chest pain, and malnutrition. In rare instances, hemoptysis may occur.

History of excessive use of oil in the form of nose drops, sprays or laxatives will suggest the diagnosis and sometimes sputum examinations will reveal oil droplets.

The principal importance of lipoid granulomas to the surgeon is confusion with other diseases which require surgical intervention, particularly bronchogenic carcinoma in persons of the older age group. It is sometimes necessary, when all other diagnostic measures have failed, to perform an exploratory thoracotomy to establish the nature of the lesion. In patients with clinical manifestation of lung destruction and distressing symptoms, the involved pulmonary tissue should be excised. It is probable that in the past certain inflammatory diseases of the lung have been considered lipoid granuloma, or lipoid pneumonia, because of cholesterol deposits associated with chronic inflammation of the lung. These fatty-like deposits are not the result of ingestion of oily materials but are part of the chronic inflammatory process associated with abscesses, bronchiectasis and other inflammatory diseases of the lung.

BOECK'S SARCOID

Boeck's sarcoid of the lung may suggest other diseases which require surgical intervention. This is particularly true of the roentgen ray appearance of the lesion. When the problem of differentiation arises, a biopsy of the lymph nodes over the anterior scalenus muscle is often useful in establishing the diagnosis. Occasionally it is necessary to perform an exploratory thoracotomy to eliminate the possibility of carcinoma or tuberculosis.

BRONCHOLITHS

Broncholiths, or lung stones, may result from calcification of inspissated material during chronic lung infections or, more commonly, from calcified lymph nodes eroding the bronchus. The common form of broncholiths is usually the result of old tuberculous infections of hilar lymph nodes.

Broncholiths may cause severe hemoptysis and atelectasis if the lumen of the bronchus is obstructed. Bronchostenosis may result from the damage to the bronchial walls.

Sometimes the lung stone will be freed and expelled by coughing. If not, removal through the bronchoscope will be necessary. Irreparable lung damage distal to the obstruction or intractable hemorrhage may require excision of the involved portion of bronchus and lung distal to the lesion.

SYPHILIS

Syphilis of the lung may occur but is extremely rare. From the standpoint of surgical treatment it is only of importance in the differential diagnosis.

Tumors

During the past decade few neoplasms have received as much attention in publications of the lay and medical press as have lung cancers. Concern regarding bronchogenic carcinomas is justifiable since the disease is common and appears to be increasing. The problems of diagnosis and treatment are therefore of utmost importance.

Benign lung tumors are uncommon. They are of interest, however, not only because of

their rarity, but because they may simulate malignant tumors.

BRONCHOGENIC CARCINOMA

Incidence. Bronchogenic carcinoma is probably the leading cause of death from visceral cancer in males. Although the lesion is not rare in females it is six to eight times more common in males. It accounts for 10 per cent of total deaths and in the United

tasis, depending upon the degree of blockage (Fig. 27). Since the bronchi are expansile, a tumor mass may partially obstruct the bronchus during inspiration and completely obstruct it during expiration. The lung distal to the tumor may become emphysematous or even have the appearance of a large cyst or bleb. The presence of localized emphysema on a roentgenogram should not distract attention away from the underlying cause.

Complete obstruction of a bronchus resulting in atelectasis may cause sufficient symptoms to give fair warning of the presence of a tumor. This may not be true, however, when segmental or subsegmental atelectasis occurs. Atelectasis in a retrocardiac position may be difficult to detect radiologically, especially on a frontal projection. Both anteroposterior and lateral full-size roentgenograms must be employed to satisfactorily visualize these lesions.

The differentiation between tuberculosis and atelectasis associated with bronchogenic carcinoma may be very difficult in some instances. The absence of tubercle bacilli in the sputum or bronchial washings should focus suspicion on the possibility of neoplasm. Failure of lobar or segmental atelectasis to improve in cases of tuberculosis which have received adequate antituberculous therapy suggests the possibility that both tuberculosis and carcinoma are present. This is particularly true in older patients.

Pneumonia and lung abscess. Bronchogenic carcinoma may commonly simulate the clinical and roentgenologic picture of viral pneumonia. These patients are often subjected to a long and ill-advised course of antibiotic therapy before the true nature of their difficulty is recognized. In any case of pneumonia which does not show signs of clearing with adequate medication, bronchogenic carcinoma should be suspected. Similarly, the radiologic appearance of pneumonia which is out of proportion to the clinical manifestations should be highly suggestive of malignancy, especially in patients over forty years of age (Fig. 28).

Symptomatic improvement and partial resolution of the pneumonia-like shadow on the x-ray film may result from antibiotic therapy. This further complicates the diagnostic problem and may give the physician a false sense of security. Pessimistic suspicion of all cases of unresolved pneumonia may circumvent a diagnostic delusion.

Bronchogenic carcinomas may produce clinical and radiologic manifestations identical with lung abscesses. Obstruction of a bronchus by tumor, resultant pneumonia and subsequent abscess formation of the involved lung may occur. Central necrosis of a large tumor mass may also closely simulate the radiologic picture of a lung abscess. The absence of an antecedent cause for pyogenic lung abscess or the location of an abscess in the upper or anterior portion of the lung

Figure 26. Hilar enlargement A, A roentgenogram which appears to be almost normal except for a suggestion of enlargement of the left pulmonary hilum B, The roentgenographic appearance of the left hilum five weeks later. The lesion was a bronchogenic carcinoma.

to a spread of malignancy throughout both lung fields or may be due to an obstructing tumor of the main bronchus or the carina. Dyspnea may also be due to a pre-existing disease such as pulmonary emphysema or heart disease and merely accentuated by the presence of the tumor.

Fever. Obstruction of a segmental or lobar bronchus by carcinoma will result in atelectasis or pneumonia of that portion of the lung. The initial symptoms may be fever, cough and chest discomfort secondary to pneumonitis or atelectasis.

Physical Findings. The physical findings in patients with bronchogenic carcinoma are extremely variable. They are dependent upon the extent of the tumor, the degree of obstruction and the presence or absence of an accompanying pleural effusion. Should a lobar or segmental bronchus be partially blocked by tumor, a persistent localized wheeze is often present and may indeed be the only positive finding to localize a tumor. When complete obstruction of a bronchus occurs the physical findings are usually those of atelectasis or pneumonia of the involved segment or lobe. Tumors located in the periphery of the lung may be asymptomatic for many months. Physical examination of the chest may be completely negative until the tumor reaches a large size or until pleural effusion occurs.

Examination of patients with suspected lung tumor should always include a diligent search of the supraclavicular and axillary areas for metastatic lymph nodes.

Röntgenologic Diagnosis. The roentgenologic manifestations of a bronchogenic carcinoma usually fall into four patterns: (1) a nodular lesion of the lung, the so-called coin lesion, (2) hilar enlargement, (3) atelectasis or (4) a shadow suggesting pneumonia or lung abscess.

Nodular lesion. Bronchogenic carcinoma may appear as a round shadow in the lung field (Fig. 25). There are often no associated symptoms and the lesion is discovered on a routine x-ray examination. The differential diagnosis of such a solitary round lesion usually lies between tuberculosis, a granuloma due to histoplasmosis or other fungus, and bronchogenic carcinoma. Skin tests and sputum examination for acid-fast organisms or fungi may be helpful but often fail to establish the diagnosis. Microscopic examination of the nodule is the only totally reliable method of reaching the correct diagnosis.

Figure 25 Nodular peripheral bronchogenic carcinoma demonstrated on a tomogram of the chest. The lesion was an adenocarcinoma.

Small solitary nodules in which there are concentric rings of calcification generally may be assumed to be granulomas due to histoplasmosis or tuberculosis and removal for diagnostic or therapeutic purposes is not mandatory. Conversely, nodular or "coin lesions" without calcification or with eccentric flecks of calcium visible by x-ray are not necessarily benign lesions. In such instances, removal of the lesion is strongly advisable.

Hilar enlargement. Radiologic evidence of enlargement of the pulmonary hilus (Fig. 26) may be caused by a tumor mass, lymph nodes or a large pulmonary artery. In this circumstance, it may be helpful to compare the x-rays with earlier chest films, unfortunately such films are often not available. Other diagnostic procedures of value are body section x-rays (tomograms, planigrams) and in some instances, angiocardioradiography. Exploratory thoracotomy is often necessary to establish the correct diagnosis.

Some bronchogenic neoplasms, particularly the anaplastic carcinoma, may appear radiologically to originate in the mediastinum. Not infrequently they may be mistaken for mediastinal tumors. Superior vena caval obstruction may occur when the neoplasm is in this location.

Atelectasis. Obstruction of a main lobar or segmental bronchus by a tumor mass may produce obstructive emphysema or atelec-

Anaplastic carcinoma. This group includes a number of different cellular types including the oat cell carcinoma and the more poorly differentiated forms of adenocarcinoma and epidermoid carcinoma. In general, anaplastic tumors appear to grow more rapidly than the more differentiated types and metastasize earlier both by way of regional nodes and by the blood stream.

Bronchiolar carcinoma (pulmonary adenomatosis, alveolar cell carcinoma). This form of bronchogenic carcinoma is relatively uncommon. It was formerly believed that this type of neoplasm arose primarily in the alveolar epithelium. However, more recent studies indicate the site of origin probably to be in the terminal bronchioles with subsequent involvement of the alveoli. Similar pathologic lesions called jagzkiekte have been observed in the lungs of sheep, horses and other animals. There is some evidence that the disease in animals is caused by a virus. This tumor has a tendency to occur in multiple sites in the lungs. Such multiple foci of tumor may be due to multicentricity of origin although some observers believe that these represent secondary implants from a single primary lesion.

Emphasis has been placed on a correlation of the cellular type of bronchogenic carcinoma with the clinical course of the disease. Some pathologists, however, have denied that the cell type has an important role in determining prognosis in survival. It is becoming increasingly evident that there are many interrelated and interdependent factors, rather than any single one, which are important in determining the ultimate course of the disease. Among these factors are histologic type, location and size of the primary tumor, presence or absence of vascular and lymphatic invasion and the status of the margins of resection if surgical removal is possible. In addition, there is a group of poorly defined "host factors" which undoubtedly play some part in influencing the operability, survival and cure rate for carcinoma of the lung.

Another concept which has recently interested many surgeons is the multicentric origin of pulmonary carcinoma. Numerous demonstrations of in situ carcinoma of the bronchus, adjacent to and away from well-defined malignant lesions, have strengthened the theory of multiple sites of origin. This is particularly true in bronchiolar carcinoma but may be applied to other cellular types

Recent analyses of patients with bronchogenic carcinomas establish that more than half have inoperable lesions when first seen by the surgeon. Of the remaining patients subjected to exploratory thoracotomy, only 40 to 50 per cent have lesions which can be extirpated. It becomes apparent that about three-fourths of all pulmonary neoplasms are advanced beyond the stages of surgical removal when the diagnosis is made.

Diagnosis. The rapid progression of most cases of bronchogenic carcinoma requires an early and aggressive approach to establishing a diagnosis. Rarely, if ever, can a policy of "watchful waiting" be condoned in the management of an unexplained pulmonary shadow.

Bronchoscopy. Bronchoscopic examination of the tracheobronchial tree may yield much valuable information concerning the extent of malignancy as well as establishing a definite histologic diagnosis.

Unfortunately, only about 30 per cent of pulmonary carcinomas can be seen through a bronchoscope. The remainder are located too far peripherally in the bronchopulmonary tree to be visualized or for biopsy.

Exfoliative cytology. The microscopic examination of sputum or bronchial washings may also be helpful in making a histologic diagnosis. The technique is not infallible, however, and requires the services of a skilled and experienced pathologist to have practical value.

Bronchography. The instillation of a radiopaque dye into the tracheobronchial tree may be of aid in visualizing an obstructing lesion in one of the more peripheral bronchi. This technique is of no value in establishing a definite diagnosis of tumor but merely serves to localize accurately the level of obstruction.

Scalene node biopsy. Carcinoma of the lung may metastasize through carinal and peritracheal lymphatics to the anterior surface of the scalenus anterior muscle. Excision of the prescalene nodes for diagnostic purposes was first popularized by Daniel. The percentage of positive biopsies will vary greatly depending upon the selection of patients for the procedure. If weight loss, pain or other findings suggest far advanced disease, study of the prescalene nodes is indicated.

Failure to find metastatic carcinoma in the prescalene nodes obviously does not exclude the diagnosis of bronchogenic carci-

Figure 28. A pneumonia-like shadow on a roentgenogram of the chest which was caused by bronchogenic carcinoma. Not only was the roentgenologic evidence suggestive of pneumonia, but the original clinical course was compatible with inflammatory disease

should make one suspicious of neoplasm

Pathology. Bronchogenic carcinoma may originate at any level in the bronchial tree. Clinical manifestations and cell types have some, but not absolute, correlation with the location of the tumor. Well-differentiated epidermoid carcinomas are more common in the larger bronchi and produce symptoms of obstruction. Peripheral tumors are usually silent until there is metastasis or invasion of contiguous structures, they are often histologically anaplastic or adenocarcinomas.

Bronchogenic carcinoma is slightly more common in the right lung than in the left, about 55 per cent of the tumors being found in the right main stem bronchus or right lung. The upper lobes are slightly more frequently involved than the lower lobes. The middle lobe is a relatively infrequent site of bronchogenic carcinoma, only about 6 per cent of all primary tumors being located in this area. Tumors arising peripherally are somewhat less common than those arising in the main or lobar bronchus levels. In many instances of more advanced tumors it is impossible to state with any certainty the exact anatomic site of origin.

Numerous classifications of bronchogenic carcinoma have been based on histologic appearance. The most practical, however, is that which divides the tumors into four major histologic categories. These categories and their relative frequency are as follows.

Epidermoid	50 per cent
Anaplastic carcinoma	32 per cent
Adenocarcinoma	15 per cent
Bronchiolar carcinoma	3 per cent

There is some variation in the relative incidence of the above histologic categories as a result of minor differences in classification by individual pathologists.

Epidermoid (squamous) carcinoma. This is the most common type of bronchogenic carcinoma. The tumor is seen predominantly in males, in a ratio of eight to one. Although it is generally stated that squamous carcinoma is relatively slow growing, there are a great number of individual factors which influence the rate of growth and the course of the disease. Metastases of epidermoid carcinomas of the lung are usually to regional lymph nodes in the hilum and peritracheal region. Direct invasion of the blood vessels, however, may occur.

Adenocarcinoma. This form of neoplasm is more common in females, comprising about half the cases of bronchogenic carcinoma seen in women. There is no statistical relationship to smoking habits. Adenocarcinoma of the lung has a tendency to occur originally as a peripheral tumor more commonly than epidermoid carcinoma. Early invasion of the blood stream with dissemination is more characteristic of this form of cancer than with the squamous carcinoma.

reveals the carcinoma has extended past the carina to the main stem bronchus of the opposite side or involves the trachea, the lesion is inoperable.

Chest wall involvement. Gross extension of the tumor into the chest wall generally precludes satisfactory surgical resection. Under extremely favorable circumstances of localized chest wall involvement, bloc removal of the lung and involved area of the chest wall may be undertaken. The ultimate prognosis in such cases is poor.

Treatment. Although a few isolated cases of spontaneous regression of pulmonary carcinoma have been reported, surgical extirpation of the tumor offers the best hope of cure at the present time. Roentgen therapy and chemotherapeutic agents, such as nitrogen mustard, offer some possibility of palliation in patients who are past the stage of operability.

Pneumonectomy and lobectomy. Total pneumonectomy with removal of the hilar lymph nodes is the surgical procedure most frequently employed for bronchogenic carcinoma. Some surgeons advocate the so-called radical pneumonectomy, which includes not only removal of the lung and hilar lymphatics, but also the lymphatic chain along the trachea and the pericardium on the involved side. The operative mortality from pneumonectomy, including the first thirty days after operation, is generally 10 per cent or less. The mortality associated with resection of a tumor when the lesion has produced invasion of the surrounding structures is considerably higher.

Under the following circumstances lobectomy is considered preferable to pneumonectomy in the treatment of bronchogenic carcinoma: (1) if the primary lesion is small and peripheral and is located well away from the interlobar fissure or adjacent lobes, (2) if there is no evidence of extension to the mediastinal lymphatics and (3) if the pulmonary reserve of the patient is such that total pneumonectomy would not be tolerated or would render him a respiratory cripple. Under these circumstances, the results from lobectomy are approximately equal to those following pneumonectomy.

Results. Analysis of large numbers of survivors after operations for bronchogenic carcinoma indicates that in patients with a localized tumor, and without evidence of vascular or lymphatic invasion, 35 per cent or more may survive five years. If, however, vascular or lymphatic invasion was demon-

strated or the tumor had extended outside the lung, five year survival statistics are generally 5 per cent or less.

The over-all five year survival of all patients with bronchogenic carcinoma is less than 10 per cent. This includes those patients who were inoperable when first seen or who were found to be inoperable at the time of exploration.

BRONCHIAL ADENOMA

Adenoma of the bronchus is a slow-growing sessile, usually circumscribed, tumor growing in the submucosal tissue of the proximal bronchi. Although its clinical course and histologic characteristics are different from those of bronchogenic carcinoma, it must be considered a potentially malignant tumor. Numerous examples of metastases from bronchial adenoma have been reported.

Bronchial adenomas are generally firm, smooth, rounded, or wormlike projections lying beneath the mucous membrane of the main stem or lobar bronchi. The tumors may be divided into two main types histologically, carcinoid and cylindroid.

The carcinoid type comprises approximately 85 per cent of all bronchial adenomas. Grossly, on cut sections, the tumor is pinkish or tan. There is usually a capsule of connective tissue around the tumor, but in long-standing lesions, invasion of the capsule or the bronchus may occur. Histologically, the carcinoid is composed of uniform, small, acidophilic cells with finely stippled nuclei. The cells resemble somewhat the carcinoid tumors of the gastrointestinal tract. Metastases from such tumors have been reported in the liver, kidneys and vertebral column.

The cylindromatous type of bronchial adenoma is less common than the carcinoid. Histologically, the cells of the cylindromatous type are less uniform, smaller and with more basophilic cytoplasm. This tumor shows a more marked tendency to invade the capsule than does the carcinoid variety. Metastases are more frequent in this type of bronchial adenoma.

Clinically, bronchial adenoma produces symptoms of bleeding or of obstruction of the bronchi. In some instances, bleeding may be exceedingly severe because of the extreme vascularity of the tumor. Tissue for diagnosis is often obtainable through the bronchoscope because of the central location of the tumor.

Treatment of bronchial adenoma must be

noma A positive scalene biopsy, however, establishes that the tumor has passed the stage of surgical curability.

The lymphatic drainage of the lung is such that the entire right lung drains to the right scalene fat pad via the mediastinal and peritracheal nodes. The upper lobe of the left lung drains to the left scalene nodes. The left lower lobe, however, may drain by way of the carinal nodes to either the right or left scalene areas

Exploratory thoracotomy. Although the previously mentioned diagnostic studies may be of value, in many cases exploratory thoracotomy may be necessary to establish a definite diagnosis. The risk of exploratory thoracotomy at present is probably no greater than that of exploratory laparotomy. The inconveniences and discomforts of the procedure are of trivial importance when compared to the urgency of diagnosis and possible successful removal of a lung cancer

Signs of Inoperability. Certain findings are generally considered evidence that a bronchogenic carcinoma has passed the stage of possible cure. In most instances, once the histologic diagnosis has been established and one or more of the signs of inoperability are present, surgical resection is not considered feasible. Under certain circumstances, however, although surgical cure cannot be anticipated, a palliative removal of the primary tumor may be performed to afford symptomatic relief of the complications of the primary tumor such as bleeding, infection or severe cough

Regional node involvement. Bronchogenic carcinoma metastasizes by way of the lymphatics to the mediastinal lymph nodes and thence to the supraclavicular lymph nodes. The nodes of the axillary region are invaded less frequently and usually later in the disease. Involvement of the prescalene nodes is indicative of metastases which have extended beyond the boundaries of surgical resection.

Nerve paralysis. Extension of a bronchogenic carcinoma into the mediastinum may cause paralysis of the recurrent laryngeal nerve on either side. Because of its anatomic position, the left recurrent laryngeal nerve is more vulnerable than the right. Paralysis of the recurrent laryngeal nerve causes hoarseness due to immobility of the ipsilateral vocal cord. Under such circumstances surgical extirpation of the entire tumor mass is not feasible.

Extension of a bronchogenic carcinoma to involve the phrenic nerve causes paralysis of

the corresponding leaf of the diaphragm. This is generally considered a sign of inoperability although under extraordinary circumstances it may be feasible to resect the pericardium and the involved nerve.

Pleural effusion. A pleural effusion associated with bronchogenic carcinoma may rarely be due to irritation of the pleura as a result of a peripheral tumor but is usually the result of tumor implants on the visceral or parietal pleura. In the latter case the effusion is frequently bloody. The presence of a serosanguineous effusion and demonstration of malignant cells in the effusion generally indicate that the tumor has passed the stage of resectability. In some instances, however, a small area of the chest wall or parietal pleura may be involved and resection of the lung and a portion of the pleura or chest wall may be technically feasible.

Pericardial effusion. Involvement of the pericardium or myocardium by direct extension of the tumor mass or by metastatic tumor may cause a bloody pericardial effusion, arrhythmias or even manifestations of cardiac tamponade. Under such circumstances, if tumor cells are demonstrated in the pericardial fluid, surgical exploration is not warranted.

Distant metastases. Primary bronchogenic carcinomas commonly metastasize to the adrenal glands, the brain, liver and kidneys. Brain metastases may be suspected when there is mental confusion or other neurologic signs. The electroencephalogram may be helpful in detecting the presence of metastatic lesions in the brain. Metastases to the adrenal gland may be difficult to detect during life. Signs of adrenal insufficiency may appear in the late phases of the disease.

The skull, spine and pelvis are frequent sites of metastases from carcinoma of the lung. Preoperative evaluation of patients with bronchogenic carcinoma should include radiographic studies of these sites in order to rule out bony metastases.

Pancoast syndrome (superior sulcus syndrome). The syndrome first described by Pancoast is usually caused by a carcinoma situated in an apical position of the lung, with involvement of the last cervical and first thoracic autonomic ganglia, producing Horner's syndrome. In addition, there is frequent involvement of the brachial plexus, causing pain in the arm and partial paralysis of the ulnar and radial nerves.

Gross extension of tumor to the contralateral side. If bronchoscopic examination

A

B

Figure 30. Metastatic melanoma. A, Large circumscribed metastasis from a malignant melanoma is shown on the roentgenogram. B, The appearance of the metastatic melanoma on the lateral projection

in these cases is poor and the patient's course is usually rapidly downhill.

BENIGN TUMORS OF THE LUNG

Hamartoma. Hamartomas are benign tumors of the lung usually located in the periphery. Usually the tumors are small, contain cartilage with variable amounts of connective tissue and are encapsulated. Occasionally, calcium may be present. The presence of calcium in the tumor may cause it to be confused radiologically with a tuberculoma. It is often impossible to differentiate a hamartoma from bronchogenic carcinoma. Thoracotomy and excision of the tumor are usually necessary to establish the diagnosis.

Other Benign Tumors. Other benign tumors of the bronchus or lung have been reported but are extremely rare. These include fibromas, lipomas and inflammatory polyps. The principal clinical manifestations are due to obstruction of a bronchus or to bleeding. They may simulate bronchogenic carcinoma, excision of the tumor and involved lung is the proper treatment.

instituted with the consideration that this is a malignant or potentially malignant lesion. Consequently, excisional biopsy through a bronchoscope or fulguration is not adequate. Surgical resection of the involved bronchus and the distal portion of the lung is the only acceptable mode of therapy. Lobectomy is usually necessary with removal of the involved bronchus and the accompanying pulmonary lobe. Occasionally pneumonectomy may be indicated. Sleeve resection and reanastomosis of the bronchus for lesions located in a main bronchus have been reported.

SARCOMA OF THE LUNG

Primary sarcomas of the lung are rare. Histologically, the tumor may be a fibrosarcoma or a leiomyosarcoma. The site of origin may be central or peripheral. In the case of the central type, the histologic picture may somewhat resemble anaplastic carcinoma.

Generally, sarcomas occur in younger age groups than do carcinomas of the lung. Severe bleeding may occur in those tumors arising in the main bronchi. Symptoms are usually absent in the peripheral type until the tumor has metastasized or invaded contiguous structures.

The treatment of sarcoma of the lung is pneumonectomy or lobectomy, depending upon its extent. If the lesion is localized, the prognosis is somewhat better than that of malignant epithelial neoplasms.

MALIGNANT TUMORS OF RETICULOENDOTHELIAL ORIGIN

Primary tumors of the lung which arise from the lymphatic or reticuloendothelial system are extremely unusual. Lymphosarcoma, or Hodgkin's disease, may occur in the lungs without other systemic manifestations. The roentgenographic appearance of these tumors is not generally diagnostic and may be confused with pneumonia or bronchogenic carcinoma. Many of these patients are operated upon with a presumptive diagnosis of carcinoma of the lung (Fig. 29).

Surgical resection of the involved lobe or lung appears to offer a fair prognosis. The use of roentgen therapy or chemotherapeutic agents as an adjunct to surgical removal has been advocated and appears to be indicated.

METASTATIC TUMORS

The lungs act as a filtering system for the venous drainage of the body. As a consequence, it is not surprising that the pul-

Figure 29. Roentgenographic appearance of lymphosarcoma of the lung. An identical x-ray shadow could be produced by bronchogenic carcinoma.

monary bed is a frequent site of metastatic implants. Metastases from primary tumors of the gastrointestinal tract, the breast, the prostate, the kidney and the adrenals are common. In addition, metastases from peripheral tumors such as melanomas or sarcomas of bone often appear in the lungs (Fig. 30).

Commonly such blood-borne metastases appear as single or multiple rounded peripheral densities seen in chest roentgenograms. The presence of multiple densities appearing in an x-ray should immediately bring up the possibility that these are metastatic lesions rather than primary bronchogenic carcinoma. Pulmonary metastases may appear years after extirpation of the primary lesion.

The presence of multiple nodules in the lung should stimulate a search for a primary lesion as well as investigation of other organs for possible sites of metastasis. If a solitary metastatic lesion is present in the lung or metastases are localized to one lobe, removal of the involved lung should be considered. Numerous cases of survival for years after resection of such localized metastases have been recorded.

Lymphogenous spread of carcinoma may occur in the lungs either from primary bronchogenic carcinoma or from distant sites such as breast, prostate or stomach. Under these circumstances there is usually a marked increase in the perivascular markings of the lung which represents involvement of lymphatic channels. The prognosis

heart disease there coexists with the primary mechanical lesion an inability of the myocardium to maintain a normal propulsive force, and in the evaluation of all patients for cardiac surgery this must be constantly borne in mind.

EXTRACORPOREAL CIRCULATION

In the present era of cardiovascular surgery an understanding of the principles of cardiopulmonary by-pass and hypothermia is a basic requirement to a discussion of the treatment of such lesions. While these methods are not used in the correction of all major cardiac defects, their fields of application are rapidly widening. Cardiopulmonary by-pass and hypothermia may be used alone or in combination.

The extracorporeal heart-lung apparatus has as its prime surgical objective the deviation of the blood from the chambers of the heart or involved great vessels to permit the repair of abnormalities under direct vision in a bloodless field while at the same time maintaining the normal state of the vital functions of the body as a whole. The goal of a relatively bloodless heart for operation is most adequately achieved if the apparatus employed can satisfactorily substitute for the pumping and oxygenating functions of the heart and lungs for prolonged periods. The artificial heart-lung when used for this purpose must remove all of the returning blood from the superior and inferior cavae, oxygenate it and pump it

into the systemic arterial circulation at exactly the same rate at which it returns through the cavae. The period of by-pass is usually limited to a period of one to one and one-half hours. For most procedures, periods of ten to thirty minutes are sufficient. Patients can be maintained satisfactorily with relatively low rates of blood flow at normal temperatures or under conditions of reduced body temperature. Low flow rates are between 35 and 50 ml. per kg. per minute. High flow rates are those between 75 and 120 ml. per kg. per minute. With higher flow rates it would appear that metabolic disturbance resulting from the procedure is less prominent and that these rates are therefore preferable. The optimal flow rate can also be determined by body surface measurement; 2300 cc. per square meter of body surface is an adequate flow rate. If the body temperature is reduced to the range of 30° C. by means of blood temperature control apparatus within the pump oxygenator system, lower rates of flow are desirable than at normal body temperatures.

Figure 1 illustrates diagrammatically the artificial heart-lung circuit. Blood removed from the cavae can flow by gravity into the oxygenator which is located 18 to 24 inches below the level of the atrium of the patient. The blood then flows through the oxygenator into the pumping mechanism. The pump returns the blood into a large artery, usually the femoral. Incorporated in the apparatus are monitoring instruments which measure

Figure 1 Diagrammatic sketch of pump oxygenator. Blood is withdrawn from cavae through flow meter and passes to oxygenator. Pneumatic pumps then propel blood to patient through a catheter in the femoral artery.

THE HEART AND PERICARDIUM

By CHARLES A. HUFNAGEL, M.D.

CHARLES ANTHONY HUFNAGEL is the son of a Kentucky physician. Educated at the University of Notre Dame and Harvard Medical School, he was trained in surgery at the Peter Bent Brigham Hospital and in the Laboratory of Surgical Research at Harvard. His investigative activities have continued throughout his career and, now at Georgetown University's medical school, he has made important contributions to the field of cardiac surgery.

The application of knowledge and techniques acquired through surgical research has played the major role in the present development of the definitive treatment of cardiovascular disease. To recognize the part which surgery properly should play in the correction of organic cardiac lesions, some of the fundamental concepts of the heart as a pumping mechanism should be emphasized.

The heart has as its prime objective the unidirectional propulsion of an adequate volume of blood through two systems—the pulmonic, or lesser circuit, and the systemic, or major circuit. The flow through these two systems must be exactly balanced since any inequality must result in fluid disequilibrium or increased cardiac work.

Thus, the heart consists of two synchronous pumping systems, each of which has a collecting chamber, an atrium, and a pumping chamber, a ventricle. As in all systems for the unidirectional pumping of fluid, there are two major elements: the propulsive force, which in the case of the heart is supplied by the ventricular musculature, and a valvular system, which pro-

pects the inlet and outlet of each of the pumping chambers to maintain the flow of fluid in a single direction.

Organic heart disease is the result of an abnormality of one or more of these major factors, the pumping force, the valvular system, shunts or obstruction to blood flow.

In congenital heart disease, the basic lesions can be divided into those in which there is an obstruction to forward flow, those in which there is an abnormal shunting of blood and those having a combination of obstruction with abnormal shunting from one chamber to another or from one circulation to another.

In acquired heart disease the lesions can be classified as valvular obstruction, valvular regurgitation, a combination of these, impairment of the blood supply to the myocardium, metabolic derangement, infection or neoplasm.

If this simplified mechanistic concept of organic heart disease is kept in mind, it removes some of the confusion which is so often associated with the classification of cardiac lesions. It must always be remembered, however, that with certain forms of

pass are rare. Those complications which do arise tend to be secondary to the disease process for which cardiopulmonary by-pass was undertaken or to a complication of the operative procedure itself, rather than to the cardiopulmonary by-pass per se.

Partial cardiopulmonary by-pass is employed to assist the failing heart in acute medical conditions. The procedure is simplified by using a large peripheral vein as a source of venous blood and returning the blood through a peripheral artery. Such a modified procedure can be accomplished under local anesthesia and may be helpful in support of an inadequate circulation.

Local perfusion of drugs to an isolated part is also possible using a similar method. High concentrations of the agent can be delivered without the systemic effect, if all returning blood is recirculated through the apparatus. This has its greatest application in the treatment of malignant tumors.

Under certain conditions while using the cardiopulmonary by-pass it is desirable to induce cardiac arrest. Cardioplegic agents which have been commonly employed are potassium citrate and acetylcholine. These drugs are introduced by injection into the aortic root after the aorta has been clamped above the site of the injection so that the full dosage is delivered into the coronary arteries. The aortic clamp is left in place during the period of the desired arrest. To restart the heart, the aortic clamp is removed and the coronary arteries perfused by the extracorporeal pumping mechanism. This results in resumption of a normal cardiac beat, usually in one to two minutes. Recovery from acetylcholine arrest sometimes occurs even prior to the reintroduction of blood into the coronary system. Anoxic arrest has also been widely employed. When the aorta is clamped the heart gradually assumes a slower rate and then ceases beating. Resuscitation of the heart is accomplished by release of the aortic clamp and restoration of the coronary circulation.

Prolonged periods of cardiac arrest with ventriculotomy appear to be associated with a varying degree of decrease in the myocardial function in the immediate postoperative period. The amount of impairment appears related to the duration of the arrest at normal temperature.

Cardiac arrest can also be accomplished by the use of cold alone. The aorta is clamped just below the innominate artery and Ringer's lactate solution at 4° C. is perfused into the coronary arteries under

systemic pressure. The surface of the heart is simultaneously cooled with Ringer's lactate at the same temperature. This produces cardiac arrest within one to two minutes. Arrest occurs when the temperature of the heart muscle reaches approximately 18° C., but electrical activity continues until below 10° C. The rewarming of the heart can be accomplished by removal of the aortic clamp and the perfusion of the heart with warm blood. Ventricular fibrillation rarely occurs during cardiopulmonary by-pass unless cardiac arrest has been used, but it is not rare following periods of cardiac arrest for more than ten minutes' duration. Fibrillation under these circumstances is readily reversible in almost all instances, providing one can maintain an adequate coronary circulation and elevate the cardiac temperature to a satisfactory level.

HYPOTHERMIA

The use of hypothermia paved the way for many important developments in cardiovascular surgery. Although for intracardiac operations it has been largely superseded by the use of the artificial heart-lung, it is still an important adjunct to the treatment of certain cardiac problems where it is used alone or with cardiopulmonary by-pass. In addition, it is a useful tool in the surgical treatment of other conditions than those of the cardiovascular system.

As early as 1944, Gross and Hufnagel showed the efficiency of body cooling to prevent spinal cord damage during periods of prolonged thoracic aortic occlusion. This work focused attention upon the principle that moderate reduction in body temperature markedly reduces the metabolic need of tissue and that this reduced oxygen need markedly prolongs the period for which the blood supply to an organ may be occluded without permanent damage. The susceptibility to damage at a specific temperature varies from one organ to another, the brain, in general, being the most sensitive. Lowering of the body temperature to levels below 30° C is associated with increased cardiac irritability which rapidly increases with temperatures below this level. At temperatures of 26° C. and lower, the incidence of ventricular fibrillation is quite high, particularly if any manipulation of the heart is carried out in this temperature range. Cessation of an effective cardiac beat usually occurs at 20 to 22° C. Cessation of all electrical cardiac activity, however, does not necessarily occur until the region of 6 to 10° C. has been

the oxygen tension, carbon dioxide tension, temperature, pH, venous and arterial pressure and the volume of flow.

In all pumping oxygenating devices an attempt is made to minimize the turbulence of blood flow, clotting and hemolysis. The surfaces with which the blood comes in contact must be free of substances which would have an undesirable physical or chemical effect upon either the formed or liquid elements of the blood and must not liberate toxic or pyrogenic materials. Certain plastics such as polyethylene, methyl methacrylate, polyvinyls or stainless steel with silicone coatings have been found most suitable for blood contact surfaces. These materials also inhibit the coagulation of blood during the period when it is outside the vascular tree.

Three types of pumping mechanism have been widely employed. These are (1) finger pumps, (2) roller pumps and (3) ventricle pumps. The latter is a chamber with a valve at its inlet and outlet which is emptied by external compression, either mechanical, pneumatic or hydraulic. All of these pumping devices when properly designed and employed can give highly satisfactory results.

A simple ventricle type pump using compressed gas as the propelling force is shown in Figure 1. Hemolysis with this type of pump is extremely low.

Oxygenating systems have depended upon the exposure of a large surface of blood to the oxygenating medium. The types usually employed have been (1) bubble type oxygenators, (2) stationary screen oxygenators, (3) rotating disk oxygenators and (4) membrane oxygenators.

Bubble oxygenators introduce small bubbles into a flowing vertical column of blood and depend upon the large surface areas of the blood gas interface to provide adequate oxygenation. Removal of the bubbles is accomplished by exposure of the oxygenated blood to a large surface coated with a defoaming agent. From the defoaming chamber a large helical tube leads the blood downward to a reservoir. During passage of the blood down the helix any small bubbles remaining rise to the surface and break. Bubble oxygenators tend to be relatively limited in oxygenating capacity in relation to their volume and two or more units may be used for patients of large size.

Stationary screen type oxygenators expose large areas of blood to a high oxygen atmosphere by the filming of blood over multiple screens in its passage through the oxy-

genator. Blood is introduced through a manifold at the top so that it will flow uniformly over each of the screens. As it passes downward it films over the large surface of the screens until it also reaches a reservoir at the bottom of the oxygenator.

Rotating disk oxygenators are composed of a series of solid disks within a horizontal glass cylinder. The disks may be corrugated to increase their surface. The lower one-third of the disk is immersed in the blood. As the disks rotate at approximately 100 revolutions per minute, a film of blood is carried upward with the rotating disk and exposed to the oxygen in the upper part of the chamber. By the time the blood reaches the outlet it is fully oxygenated. These are highly efficient oxygenators and like the stationary screen oxygenators do not introduce bubbles into the blood.

Membrane type oxygenators depend upon the transmission of oxygen and carbon dioxide through a membrane of Teflon, polyethylene or silicone rubber. These materials have high rates of oxygen transmission and there is never a direct contact between the blood and a gaseous medium. Thin layers of blood are passed between the membranes which are in a high oxygen atmosphere. The volume in these oxygenators tends to remain relatively constant, whereas the amount of blood in the other types of oxygenators may under some conditions vary considerably. The membrane oxygenator is still in the earlier phases of its development, but it appears to have certain theoretical advantages which are particularly helpful. At the present time in experienced hands all of these types of oxygenators are producing satisfactory results.

Disposable oxygenators of several types are being developed to simplify the procedure further. Blood used in the heart-lung apparatus is heparinized when it is secured from donors rather than being taken in an acid citrate dextrose medium.

When the extracorporeal by-pass is used, patients are heparinized prior to the introduction of catheters into the cavae and the systemic artery. 2 mg of heparin per kg. of body weight produces adequate heparinization. At the conclusion of the by-pass the anticoagulant effect of the heparin is neutralized by the administration of protamine sulfate. The complications following by-pass are hemorrhage, air embolism, acidosis, hemolysis and pulmonary complications. In experienced hands the complications secondary to the use of cardiopulmonary by-

pulmonary bed. The aortic pressure gradually rises so that shortly after birth the aortic pressure is slightly higher than the pulmonary. Thus, in neonatal life, flow through the ductus is minimal and, in the normal course of events, anatomic closure of the ductus occurs in the majority of infants between two and six weeks following birth.

Failure of the ductus to become obliterated results in the persistence of the communication between the pulmonary artery just to the left of its bifurcation and the aorta at a point just distal to the left subclavian artery. As the aortic pressure continues to increase, there results a shunt from left to right, that is, from the aorta to the pulmonary artery. The amount of blood which is so shunted will vary with the size and position of the ductus and with the relationship of the pressures in the aorta to the pulmonary artery. In most instances the aortic pressure remains higher than the pulmonary pressure throughout all phases of the cycle, but the greatest flow tends to occur during systole.

In adults, the amount of blood which is shunted from left to right in this way varies from 1 to 10 liters per minute. This lesion therefore results in increased work for the left ventricle since a portion of the blood which is ejected into the aorta is lost in being pumped back again into the pulmonary circuit and is returned to the left side of the heart. There is an increased pulmonary arterial flow, increased left ventricular work and a decreased effective systemic outflow.

A reversal of shunt sometimes occurs in the presence of a patent ductus and this is characterized by pulmonary hypertension and cyanosis of the lower extremities, because of shunting of blood from the unsaturated pulmonary circuit into the systemic circuit. The upper extremities and head are not cyanotic since all of the blood which flows through the aortic root is fully saturated. In such instances the pulmonary resistance is extremely high.

Patent ductus is frequently associated with other lesions of the heart, particularly with coarctation of the aorta, ventricular septal defect, transposition of the great vessels and truncus arteriosus. The ductus arteriosus also remains patent for a time in association with the tetralogy of Fallot and the symptoms of tetralogy become more marked when the ductus closes.

The symptoms of patent ductus arteriosus vary greatly. There may be no symptoms, but those which do appear are associated

with left ventricular failure, pulmonary engorgement or endarteritis. Heart failure in infancy or childhood should always be investigated for the possible presence of a patent ductus arteriosus. Subacute bacterial endarteritis is a relatively common complication of this lesion and may be associated with chills, fever, malaise and emboli.

Physical examination shows findings which are classically confined to the cardiovascular system. A machinery type of murmur is present over the second left intercostal space in 95 per cent of patients. This murmur is to and fro with a systolic accentuation and is almost pathognomonic, but it is also present in association with aorticopulmonary fistula—a communication between the base of the aorta and the root of the pulmonary artery—and rarely in patients with aortic insufficiency associated with a ventricular septal defect. A venous hum, coronary arteriovenous fistula or pulmonary arteriovenous fistula may produce a similar murmur. In some patients, the murmur may be purely systolic. There may be no murmur heard when the pulmonary and aortic pressures are almost equal.

The heart size tends to be normal or slightly larger than normal. The pulmonary second sound is accentuated if there is pulmonary hypertension. If the ductus is small to average in size, the blood pressure may be entirely within normal limits. Because of the valveless communication between the aorta and pulmonary artery, a low diastolic pressure and a wide pulse pressure are frequently noted. When the widening of the pulse pressure is present, the pulse is Corrigan in type.

On x-ray films the cardiac contour is usually normal. The pulmonary markings are slightly accentuated in some cases. Fluoroscopy will show pulsations of the secondary pulmonary arteries with "hilar dance." Angiocardiography may reveal the presence of the ductus by direct visualization from the aorta or it may show reopacification of the pulmonary vessels after the blood has reentered the pulmonary circulation from the aorta. Direct aortography may show opacification of the pulmonary artery after direct injection of a contrast medium into the aorta just distal to the left subclavian artery.

Cardiac catheterization should be employed in patients in whom doubt of the correct diagnosis exists. The characteristic finding is increased oxygenation in the pulmonary artery. In general, pulmonary arterial pressures are not usually greatly in-

reached. It would appear that in order to lower the body temperature safely below 30° C., cardiopulmonary by-pass should be used as an adjunct to maintain effective circulation during these critical periods when ventricular fibrillation and cardiac standstill may occur and to be able to raise satisfactorily the temperature of the body for resuscitation. However, it has been possible by external means alone in a few cases to lower the body temperature to the point of cardiac arrest and satisfactorily revive the patient. It would appear probable that in the near future it will be possible to maintain individuals in a prolonged state of suspended animation by the combined use of extracorporeal circulation and control of body temperature.

When hypothermia is used alone body temperature of 30 to 32° C. would appear optimal, combining the maximal benefits with minimal risk. At this temperature the body metabolic requirements are reduced by approximately 50 per cent. Cardiac irritability remains essentially normal. Hypothermia may be induced by external cooling or by cooling of the blood. The external means is most commonly employed. Reduction of body temperature is accomplished by reduction of the environmental temperature under anesthesia. Sufficient anesthesia or other drugs must be used to abolish shivering, since this is a mechanism for heat production. Cooling may be accomplished by immersion of the patient in a bath of cold water with care not to allow contact of ice with the skin. Because of the high heat conductivity of water it is the most effective simple mechanism for the transfer of heat from the body to the bath. Those methods which employ only dry cold are much slower than those in which the body is in direct contact with a water medium. An adult patient can be cooled by external means to a body temperature of 32° C. in approximately one hour when an efficient cooling system is used. There is usually some drift of the temperature downward after the initial cooling phase and means must be available to prevent this drift from being excessive. A mattress placed on the operating table through which hot or cold fluid can be circulated is the method usually employed for the final regulation of the temperature during the operative procedure itself. Following completion of that part of the operative procedure for which the lowered temperature is required, the patient can be immediately rewarmed by passing warm

fluid through the mattress. Some surgeons have used a diathermy coil around the pelvis for rapid rewarming in selected cases.

Systems for the cooling of blood have employed the principle of removing blood through an artery or vein, passing it over a large surface in contact with a cold environment, and then returning it to the body by a pumping mechanism. The devices which are used to regulate the body temperature under these circumstances are known as heat exchangers. Most employ the principle of multiple metal tubes of small diameter through which the blood circulates. The tubes are surrounded with a fluid medium which can be heated or cooled to the desired degree. Other heat exchangers pass the blood over a series of tubes through which the cold fluid circulates. In such devices the same principles which apply to the artificial heart-lung machine are employed. In such heat exchangers it is possible to lower body temperature at rates of 1° per minute and to rewarm at approximately one-half this rate. These devices give accurate and rapid control of the body temperature at all times.

Drugs may be used to reduce ventricular irritability during intrathoracic operations. Prostigmine, Xylocaine, quinidine and Pronestyl have been advocated for prevention of ventricular fibrillation under hypothermia. Block of the sinoatrial node with procaine has also been employed. While these measures appear helpful, particularly in the temperature range of 28 to 30° C., they are less effective at lower temperatures.

With refinements in the methods of hypothermia and the extracorporeal circulation, it is apparent that many new procedures are now possible which were previously beyond the surgeon's technical ability.

PATENT DUCTUS ARTERIOSUS

The ductus arteriosus is normally patent during intrauterine life and permits a large proportion of the right ventricular blood to pass from the pulmonic circuit into the systemic pathway by way of the descending aorta. The lungs at this period are relatively unexpanded and the volume of blood flow through them is small because of the high pulmonic resistance. At birth, with the expansion of the lungs and the assumption of the oxygenation function by the lungs, the resistance in the pulmonary circuit is greatly diminished. With this decreased resistance in the capillary bed of the lungs, the pulmonary pressure decreases and the outflow of the right ventricle passes through the

left subclavian artery. This lesion is embryologically related to truncus arteriosus. In the case of aortic septal defects the aortic and pulmonary valves are normal in development in most cases, but there is a partial defect in the septum between the aorta and the pulmonary artery. If the septum between the aorta and the pulmonary artery is completely absent inferiorly to the level of the aortic and pulmonary valves, the lesion is a truncus arteriosus. In the latter case, a single valve may be present at the base of the truncus and the origin of the pulmonary blood supply is highly variable.

The dynamics of aortic septal defect are similar to those of a ductus. Aortic septal defects may be large and when this is the case there may be major elevations of pulmonary pressure.

When pulmonary congestion and hilar dance are present, the heart tends to enlarge gradually to a greater degree than that seen in patent ductus because the communication is usually larger. Retrograde aortography may demonstrate the lesion well. Cardiac catheterization may further delineate the lesion by showing high pressures in the common pulmonary artery and increased oxygenation in the main pulmonary artery in contrast to its branches. Passage of the catheter through the defect into the ascending arch or into the transverse arch may be diagnostic.

A continuous murmur associated with patent ductus is usually heard, but this murmur is heard in a slightly lower position than in patent ductus and tends to radiate to the right.

Treatment of aortic septal defects is closure by suture under direct vision, using extracorporeal circulation. The aorta and pulmonary artery are separated to delineate the communication. By-pass is used and the vessels are divided and the openings remaining at the site of the communication are closed by sutures. The risk of operation is low except in those individuals who have had major degenerative changes in the pulmonary artery associated with a large lesion of long standing.

The prognosis without operation is more serious than in patent ductus. The operative procedure offers total correction of the lesion.

COARCTATION OF THE AORTA

Coarctation of the aorta may be divided into two anatomic varieties—preductal and postductal. Preductal coarctation has been

termed "infantile" and is an obstruction of the aorta proximal to the insertion of the ligamentum or ductus arteriosum. Postductal coarctation ("adult") is associated with obstruction distal to the ligamentum. The confusing designations of "adult" and "infantile" should be abandoned but are mentioned since they are used throughout the early literature and to some extent at present.

The common form of coarctation is postductal in type and consists of a narrowing or complete obstruction of the aorta just distal to the left subclavian artery and distal to the insertion of the ligamentum arteriosum. The ductus arteriosus is usually obliterated. The aorta proximal to the constriction tends to be normal in size and the major proximal branches of the aorta are greatly enlarged as are the intercostal arteries distal to the obstruction. The left subclavian artery may be enlarged to approximately the size of the aorta itself. When the ductus remains patent, it usually communicates with the proximal aortic segment.

The area of aortic obstruction is usually short and the aorta is somewhat kinked at this point. The constriction varies considerably in diameter from complete obliteration to a lumen of 1 to 5 mm. in diameter. Frequently the area of narrowing is long and in adults it may be several centimeters in length. Distal to the obstruction, the aorta may be extremely hypoplastic, normal or dilated. Figure 3 shows some of the common variations of the lesion and their correction.

Aneurysms sometimes occur distal to the obstruction in both children and adults (Fig. 3D). This lesion is most often seen associated with a small lumen in the area of coarctation and is related to the jet effect of blood passing through a very small lumen. The conversion of high forward velocity to lateral pressure distal to the obstruction results in excessive stress on the lateral aortic wall and leads to the development of aneurysm. The intercostal arteries are greatly dilated and tortuous. One or more of these vessels may be aneurysmal at their junction with the aorta.

In addition to the usual site of constriction just below the left subclavian artery, cases of coarctation have been reported in the mid and low thoracic aorta and in the abdominal aorta. When they occur below the usual site, the area of constriction tends to be quite long.

The etiologic background of coarctation

Figure 2 Patent ductus arteriosus. The two principal variations of patent ductus are both corrected by division and suture

creased. The electrocardiogram may show normal tracings or left ventricular preponderance.

Obliteration of the isolated patent ductus is accomplished by division of the ductus and suture of the cut ends (Fig. 2). Multiple ligation of the ductus has also been advocated and is carried out in some clinics. It is preferable to proceed with operation in childhood, but elective operation should be advised whenever the diagnosis is made after the patient is two years old. In the newborn period, the establishment of the diagnosis is difficult and operation is not done unless there is evidence of congestive failure or other complications which endanger the patient's life.

Contraindications to treatment are primarily general diseases which make any surgery hazardous. In the absence of symptoms in the patient over fifty years of age, correction of a ductus is not advised, but if serious signs or symptoms occur operation should be performed in individuals of any age. When the ductus is serving a compensatory function, its closure is obviously indicated only when the associated lesions are also corrected. When bacterial endarteritis is present, attempt at medical cure should be made. If a cure of the subacute endarteritis is obtained by medical therapy, elective operation should be carried out in approximately six months. Surgical intervention should be done immediately if there is evidence that antibiotic therapy is ineffective.

Untreated patent ductus arteriosus has as possible complications congestive heart failure, acute bacterial infection in the region of the ductus, development of aneurysm of the ductus, the pulmonary artery, or the adjacent aorta, and development of pulmonary hypertension.

Operation in childhood carries a mortality rate of approximately 1 per cent. The operative risk is between 1 and 2 per cent in adult patients who have pulmonary pressures which are normal or only slightly elevated. When pulmonary pressure is normal or moderately elevated, the indication for operation is its presence. When pulmonary pressure is elevated but less than aortic pressure, there is an urgent indication for operation. In some instances there may be transitory reversal of flow from the pulmonary artery to the aorta and operation is also indicated. When permanent reversal of the shunt has occurred, operative risk is markedly increased. This is particularly true in the adult. Opinion is divided as to whether closure of the ductus can produce benefit after permanent reversal of the shunt has occurred. It is the general opinion at the present time that if the pulmonic pressure cannot be lowered to levels less than the aortic pressure, closure is contraindicated.

AORTIC SEPTAL DEFECTS

Aortic septal defects are less common congenital anomalies in which a communication is present in the common pulmonary artery beyond the aortic valve and proximal to the

X-ray examination of the chest demonstrates a normal or enlarged cardiac silhouette. There is frequently a diminished aortic shadow in the region of the aortic arch, but the lack of the normal aortic prominence is variable. Notching of the ribs seldom is noted in childhood, but it is commonly seen after the age of ten. Angiocardiography or direct aortography will demonstrate the zone of constriction.

Electrocardiography usually shows left ventricular hypertrophy, left axis deviation or left ventricular strain.

Demonstration of the anatomic lesion in the patient under forty years of age is an indication for operation. Evidence of continuing cardiac enlargement or signs of congestive failure also are indications for operation. In the older age groups, signs of severe hypertension, cardiac strain or recent bacterial endarteritis are indications for operation.

In the infant, uncontrollable congestive failure sometimes necessitates operation. An attempt should be made to control the failure medically since many infants, after their initial bout of failure, can be maintained well on good medical management until late childhood.

The optimum time for operation is when the patient is between six and twelve years of age. Operative mortality and complications are higher in infants and in patients beyond the age of forty years. When severe aortic insufficiency is also present, operation for both lesions should be done simultaneously. In the presence of aneurysm, operation should be performed with resection of both the aneurysm and the coarctation.

Excision of the area of constriction with end-to-end anastomosis is the simplest and most effective form of treatment of coarctation of the aorta. In the usual case, the aorta is freed from its bed through a left thoracotomy. The area of the stricture is isolated and the ligamentum arteriosum is divided. If the ductus is patent, the ends are oversewn in the usual fashion. Noncrushing clamps are applied to the aorta above and below the area of constriction, and, after excision of the constricted segment, an end-to-end suture is carried out. In children under the age of ten years, it is almost always possible to accomplish this type of procedure. Occasionally the presence of an aneurysm may necessitate considerable mobilization of the aorta in order to get the ends together.

In some instances, and particularly in

adults, a long constriction or large aneurysm of the aorta is seen and, because of the inelasticity of the aortic wall, it is not possible to bring the ends directly together. A homograft or arterial prosthesis can be used to bridge the gap between the aortic ends so that the anastomosis can be made without excessive tension (Fig. 3B to D). Arterial homografts have been used for this purpose but are now only occasionally employed. Flexible cloth prostheses of Dacron or Teflon have been more satisfactory. It is undesirable to use a prosthesis or homograft in infants or young children because of the lack of growth of these replacements. The elasticity of the aorta in the younger age groups is so great that a direct anastomosis can be accomplished in almost all postductal coarctations.

Surgical correction of the preductal type of coarctation may be accomplished by direct anastomosis, utilizing the aortic end of the ductus. The preductal type is frequently associated with a long area of narrowing, involving either the distal transverse aortic arch or the entire isthmus of the aorta. In these instances an additional aortic arch is created by suturing a vascular prosthesis or homograft proximal to the area of obstruction in the ascending arch and making a second end-to-side anastomosis to the aorta beyond the area of coarctation. Those vessels which are supplied by the narrowed, but not completely obstructed, arch continue to carry blood without interruption.

Results of surgery in coarctation of the aorta of the postductal type are excellent. The blood pressure of the upper extremities can be expected to fall to normal limits and the blood pressure in the lower extremities rises. Symptoms of congestive failure are relieved. The mortality for operations of coarctation without complicating features is under 5 per cent and only slightly higher in those associated with long strictures or aneurysms. The major complications are infection of the suture line, renal failure and occasionally neurologic complications associated with interference to the blood supply of the lumbar cord.

VASCULAR RINGS

Anomalous development of the aortic arch and its branches leads to a number of conditions which produce compression of the trachea, esophagus or both. The most common of these conditions are double aortic arch (Fig. 4), origin of the right subclavian artery from the left side of the aortic arch,

Figure 3 A, The common postductal coarctation is shown before and after direct repair. B, Combined preductal aortic narrowing with obstruction of the left subclavian artery. Repair with a prosthesis shows removal of subclavian obstruction. C, Coarctation with patent ductus arteriosus. The repair utilizes a part of the aortic end of the ductus. D, Postcoarctation aneurysm and its correction with a prosthesis.

of the aorta is unknown. Many theories have been advanced to relate the presence of coarctation to the insertion of the ductus, but none are generally acceptable.

Collateral circulation in the adult type of coarctation is derived through the subclavian arteries and their branches, the internal mammary artery, the costal cervical trunk, the superior intercostal artery and the thyrocervical trunk, the transverse cervical artery, the transverse scapular artery and the intercostal arteries. The continuation of the internal mammary as the inferior epigastric artery anastomoses with the external iliac artery and the anastomoses between the inferior epigastric arteries and the lumbar arteries form additional channels.

In some patients the left subclavian artery, instead of being enlarged, is hypoplastic or is involved in the coarctation. The collateral circulation will be entirely right sided in such subjects. When the coarctation lies in

the low thorax or abdomen, the upper collateral channels are distinctly less well developed than when the coarctation is high. Collateral circulation may be quite well developed at birth, but the size of the collateral channels appears to increase out of proportion to the growth of the child and, therefore, becomes much more apparent in adult life.

There may be no symptoms early in life or even well into adulthood. In infants, however, if they do appear, they are chiefly those of congestive failure or of bacterial infection. Later in life, additional symptoms are associated with cerebral hypertension and peripheral decreased flow. They include dizziness, headaches, syncope, shortness of breath, paralysis or ocular hemorrhage. Coldness and fatigue of the lower extremities and intermittent claudication may also be noted.

Physical examination characteristically reveals elevated blood pressure in the upper extremities and lowered blood pressure in the legs. In a considerable number of patients the blood pressure in the upper extremities will be normal or only slightly above normal, but palpation of the femoral pulses will show them to be greatly diminished or absent and the blood pressures in the legs will be lower than in the upper extremities. If the left subclavian artery is hypoplastic, the blood pressure in the left arm may be greatly lower than that in the right. If the right subclavian artery rises from below the coarctation, the blood pressure in the right arm will be lower than that in the left.

Examination of the chest may show a slight to great enlargement of the heart. There may be no murmurs present, but in most patients a systolic murmur is heard in the aortic area. This murmur is transmitted through to the back and the interscapular region. The murmur is usually maximal near the area of constriction. If the coarctation is in an unusual position, the site of the maximal murmur may give some clue as to whether it is low in the thorax or abdomen. If a diastolic murmur is also present, this is usually associated with a regurgitant bicuspid aortic valve or patent ductus arteriosus. The presence of enlarged collaterals may be noted most easily over the interscapular region in back by palpation and visual examination. Murmurs heard over the back, both on the right and left, may frequently be obliterated by compression of the dilated intercostal arteries.

um in the esophagus and trachea. Angiography may be necessary to elucidate further the more complex lesions by visualization of branches of the aortic arch.

Surgical treatment is directed toward the decompression of the trachea and esophagus. When a double aortic arch is present, one arch is usually larger than the other. By a careful dissection of the two components, one can determine the origin of the blood supply to the head. It is then possible to isolate the smaller branch and, following the application of noncrushing arterial clamps, to divide this limb of the arch from the main aortic arch near the point at which the two components unite. This releases the circular constriction and relieves the compression.

When the ligamentum arteriosum is the dominant feature producing the ringlike obstruction, the division of this ligament itself is sufficient to release the compression. Division of an aberrant right subclavian artery will also remove the constriction caused by its posterior course. Reimplantation of the right subclavian artery into the right portion of the aortic arch can also be carried out without difficulty.

Suspension of the aortic arch or one of its branches anteriorly to relieve the compression from its posterior displacement may be necessary in some cases. This is particularly helpful in the lesions in which the carotid arteries arise from the innominate or from a left origin of a right innominate.

Operation must often be carried out in infants whose general condition is extremely poor because of the presence of pulmonary infection from aspiration of esophageal contents. This complication represents one of the serious hazards of the condition which jeopardizes life. If the diagnosis can be made prior to the development of such pulmonary complications, the over-all results are uniformly good and the prognosis thereafter is excellent.

PULMONIC STENOSIS

Pulmonic stenosis is of four general types: valvular, infundibular, pulmonary arterial and combined.

Stenosis of the pulmonary valve associated with another major lesion or lesions is one of the most frequently occurring congenital cardiovascular defects. Isolated pulmonary stenosis

septal defect. However, these terms are also applied to pulmonic stenosis associated with a patent foramen ovale.

If the pulmonic stenosis exists alone, cyanosis is not present except as an accompaniment of extreme heart failure. When a patent foramen ovale is present, cyanosis occurs and the amount of shunting from right to left determines the degree of cyanosis. In such patients the patency of the foramen ovale is maintained by a high right atrial pressure and the pulmonic stenosis is usually the major lesion.

In the valvular type, the valve cusps are fused to a varying degree, producing all gradations from slight obstruction to almost complete occlusion of the right ventricular outflow tract. The cusps are usually united in a conical or dome-like structure with an orifice at the apex. Immediately distal to the valve, the pulmonary artery is dilated in the vast majority of cases. This dilatation distal to the area of obstruction is similar to that which is seen in coarctation of the aorta and is also related to high velocity flow through a narrow orifice into an area of lower pressure.

The second variety is termed infundibular stenosis. In this malformation, a ridge of hypertrophied muscle, the crista supraventricularis, or a membranous diaphragm narrows the pulmonary outflow tract (infundibulum) of the right ventricle. The infundibular type of stenosis may be immediately subvalvular or it may be quite low in the ventricle. Between the area of infundibular obstruction and the pulmonary valve is a zone which is sometimes referred to as the third ventricle. In this area the ventricular muscle is usually thin, in contrast to the hypertrophied muscle of the right ventricle proximal to the obstruction.

Obstruction to the right ventricular outflow tract may be caused by a variant of infundibular stenosis in which the valvular structures are normal but in which there is hypertrophy of the muscle of the right ventricle over a long distance below the valve. No zone of localized narrowing is manifest, but marked obstruction to flow exists.

In contrast to this are tetralogy of Fallot and other defects in which there is communication between the right and left sides of the heart with right-to-left shunts, for in these the systemic blood is highly unsaturated.

In isolated pulmonary stenosis, approxi-

Figure 4. A vascular ring formed by a double aortic arch illustrating encroachment upon the tracheoesophageal space

origin of the left common carotid from the innominate artery, origin of the left common carotid from the right side of the aortic arch and a right aortic arch with a left ligamentum arteriosum

Compression is not only caused by the vessels themselves, but may be associated with fibrous bands or remnants of other vessels which accompany the arteries themselves.

A double aortic arch is produced by the persistence of both right and left primitive arches, the anterior representing the left and the posterior representing the right. The ascending aorta bifurcates and one portion passes behind the esophagus and the other in front of the trachea to reunite to form a single descending aorta at the level of the left subclavian artery. Either the anterior or the posterior branch may be the larger and the major arterial trunks arise from either or both arches.

The right subclavian artery may arise as the last branch of the aortic arch. In this anomaly, the right common carotid is the first branch of the arch, the left common carotid is the second, the subclavian artery is the third and the right subclavian artery last. The right subclavian artery then passes to the right and posteriorly behind the esophagus and upward to the arm. This posterior course compresses the esophagus

between the aortic arch and the anomalous vessel.

When the left common carotid artery arises from the innominate artery, it passes anterior to the trachea and upward into the neck as the right common carotid artery pursues a similar course and the esophagus and trachea are compressed between these two major vessels. Similarly, when the innominate artery rises from the left side of the arch it passes to the right upward into the neck and it compresses the trachea as it passes over it anteriorly.

When a right aortic arch persists, the ligamentum arteriosum has its insertion to the left of the common pulmonary artery in its usual site and as the arch passes behind the trachea and esophagus it is encircled posteriorly by the right aortic arch, anteriorly by the pulmonary artery, to the left by the ligamentum arteriosum and behind by the transverse portion of the aortic arch. This gives a complete ring which may obstruct either the trachea or the esophagus.

As a result of the chronic tracheoesophageal compression, the symptoms may be either predominantly respiratory or esophageal. Dysphagia is often a prominent symptom and the continued regurgitation of esophageal contents may give rise to considerable pulmonary infection subsequent to its aspiration. Evidence of tracheal obstruction is associated with wheezing, crowing respirations and is most often evident in association with eating. In infancy, symptoms may be noted only at the time of ingestion of food and, at these times, cyanosis and extreme respiratory distress may appear. Retraction of the suprasternal and supraclavicular spaces with stridor is common.

A double aortic arch, a right aortic arch with a persistent ligament and an anomalous origin of the right subclavian artery tend to produce severe symptoms. In adults, the symptom of dysphagia tends to be more prominent than do respiratory symptoms.

Instillation of iodized oil into the esophagus shows characteristic defects of esophageal compression on the x-ray film. Barium should not be used to demonstrate these defects in infants because of the danger of aspiration. The presence of a right aortic arch can be determined by the side upon which the aortic knob presents its esophageal impression. The presence or absence of constriction of the trachea and esophagus can be shown by the use of a contrast medi-

Figure 6 Resection of infundibular pulmonic stenosis through a right ventriculotomy incision.

valve and infundibulum require exposure of the outflow tract of the ventricle and the pulmonary artery. When valvular stenosis is present, a thickened obstructed valve can be palpated through the pulmonary artery and there is usually dilatation just above the obstructed valve. When the heart has been emptied of blood, an incision is made in the pulmonary artery immediately distal to the valve. The valve is seen as a conical volcano-like structure with a small opening in its center. The pulmonary valve is reconstructed by incisions in the valve to open it to the annulus. The heart is then filled with blood. Pressures are recorded in the ventricle and distal to the valve. If no gradient exists, an adequate valvulotomy has been accomplished. If a gradient still persists, the incision in the pulmonary artery must be reopened and the valve further mobilized until the gradient disappears. Infundibular obstruction is also corrected under direct vision. The use of cardiopulmonary by-pass is ideal for this purpose. If the obstruction is of the localized type it is removed by excision after ventriculotomy (Fig. 6). When a long area of hypertrophied muscle presents a physiologic obstruction to flow, the outlet tract of the ventricle is incised without cardioplegia. Any localized obstructing hypertrophied muscle is removed by excision and the pulmonary outlet tract is widened

by the use of a ventricular patch. Ovoid patches of Ivalon, Teflon or combinations of these materials are sutured into the longitudinal incision in the ventricle to produce the widening of the pulmonary outlet tract. It is sometimes necessary to carry this through the annulus of the pulmonary valve and into the base of the pulmonary artery. This type of widening is also used in some cases of tetralogy of Fallot. The use of shunting procedures in isolated pulmonic stenosis is contraindicated. The results of direct operations have been excellent and the mortality rate of operation is low.

TETRALOGY OF FALLOT

Tetralogy of Fallot is a complex anomaly in which pulmonary stenosis, a high interventricular septal defect, overriding of the aorta and right ventricular hypertrophy are present. Pulmonic obstruction may be valvular, infundibular or in the artery itself. Valvular stenosis is similar to that which is found in pulmonic stenosis. The obstructive component may also be either hypoplasia of the pulmonary artery or a hypertrophied supraventricular crest.

The severity of the lesion depends upon the summation of the factors of the degree of pulmonary obstruction, the size of the interventricular septal defect, the degree of overriding of the aorta and the presence or absence of a patent ductus arteriosus and/or other large bronchial or mediastinal collaterals to the lung.

The degree of peripheral arterial unsaturation is determined by the amount of right ventricular blood which is expelled into the aorta. Arterial oxygen saturation of less than 60 per cent produces severe cyanosis. Polycythemia is usually present and intravascular clotting in the cerebral or pulmonary vessels is not uncommon. The greater the degree of polycythemia the more frequent is the occurrence of this complication. Patients in the older age groups may develop bronchial and other collateral circulations from the chest wall to the lung which form plexiform systemic-pulmonic anastomoses. An extremely

Thus, under these circumstances intravascular clotting is frequent, but the failure of the formation of a firm clot may lead to considerable bleeding during and after surgery. With an extremely high hemoglobin, the 5 gm. per 100 cc. of reduced hemoglobin necessary to produce cyanosis is more easily

mately 85 per cent of all cases are valvular in type. In tetralogy of Fallot, the reverse is true, the majority being of the infundibular variety.

The symptoms are primarily those of decreased pulmonary flow. The patient has ease of fatigue, dyspnea on mild exertion or syncope. Patients may show some retardation of general development, but this is not always present. Cyanosis is usually absent, but if the foramen ovale remains patent, cyanosis may become marked. If the foramen ovale closes, cyanosis is absent. A history of squatting is seldom obtainable.

Cardiac enlargement of varying degrees may be present. There may be bulging of the precordium due to hypertrophy of the right side of the heart. A systolic murmur of harsh character in the second left intercostal space is characteristic. A systolic thrill is frequent. Radiation of the murmur is to the left and to the back. The pulmonary second sound is usually diminished. Signs of congestive failure occur and, if cyanosis is a dominant feature, clubbing of the fingers may also be present.

Chest films show enlargement of the right atrium and right ventricle. The pulmonary conus is prominent because of enlargement of the main pulmonary artery just distal to its exit from the ventricle. The periphery of the lung fields is relatively avascular. Angiocardiography will show delay in emptying of the right ventricle and a dilated pulmonary artery distal to the valve. Injection of contrast medium directly into the right ventricle may demonstrate either infundibular or valvular type of obstruction. The electrocardiogram shows right axis deviation and right ventricular hypertrophy.

Cardiac catheterization exhibits high right ventricular pressures and a sharp fall as the catheter enters the pulmonary artery. No shunt in the ventricle is demonstrable. If the foramen ovale is patent, the catheter can enter the left atrium or pulmonary veins. Pressures in the right ventricle may be elevated to approach systemic levels. The important diagnostic criterion is the presence of a gradient between the pulmonary artery and the right ventricle. Catheterization studies show that the intensity of the murmur is not directly related to the degree of obstruction. Thus, patients with extremely high right ventricular pressures and very low pulmonary artery pressures may have relatively low intensity murmurs and those who have relatively small degrees of obstruction may have loud murmurs.

The over-all prognosis in pulmonary stenosis is related to the degree of obstruction. Patients who have relatively small degrees of obstruction do well for prolonged periods and may show no disability in spite of the presence of very loud murmurs. Patients with a high degree of obstruction tend to develop congestive failure early and to have severe symptoms. If operation can be advised before the appearance of severe symptoms and congestive failure, the operative risk is extremely low. If congestive failure or a patent foramen ovale is present with severe cyanosis, operative mortality is markedly increased.

The surgical treatment of isolated pulmonary stenosis is directed toward the removal of the obstruction in the valve or in the outlet tract of the right ventricle. Valvular obstruction may be relieved by pulmonary valvulotomy or pulmonary valvuloplasty. Patients with congestive failure, right ventricular pressures of over 70 mm. of mercury, or severe symptoms should be selected for operation.

Operative treatment of pure valvular stenosis is best accomplished by direct visualization of the valve (Fig. 5). Hypothermia or cardiopulmonary by-pass is used to obtain a dry heart. All operations on the pulmonary

Figure 5 Congenital pulmonic valvular stenosis as seen at operation. Note that the incisions are carried to the edge of the annulus.

ated into the pump oxygenator and a right ventriculotomy is performed. The interventricular septal defect is closed and the overriding corrected by the closure. Patches of Ivalon, Teflon or Dacron are used to add substance to the deficient septum. The stenosis of the pulmonary outlet tract is corrected by resection of the infundibulum, widening of the outlet tract or opening of the pulmonary valve as indicated by the particular lesion or combination of lesions. Cardiac arrest may be used in selected instances but is generally avoided. Care is required in closure of the septum to avoid placing stitches in the bundle of His. The results of total correction are excellent and it is anticipated that the problems which arise fol-

lowing the shunting operations will not be seen. Complications of open operation are infections in the suture line, failure to obtain complete closure of the septal defect or failure to remove completely the pulmonary obstruction. The risk of such procedures has markedly decreased and approximates that of the indirect operation.

ATRIAL SEPTAL DEFECTS

Atrial septal defects exist in a wide variety of forms which may be grouped into the following classifications: absent septum (single atrium), persistent ostium primum, persistent ostium secundum, atrioventricularis communis. A persistent patent foramen ovale with an incompetent valve or absent

Figure 7 A, Direct operation for tetralogy of Fallot Closure of the septal defect and resection of infundibular obstruction are shown. accumulated than in the patient with a normal hemoglobin level.

Early in neonatal life, the ductus arteriosus tends to remain open and during this period the patient may exhibit relatively few signs and symptoms. Closure of the ductus may be heralded by increasing cyanosis, dyspnea and syncope. Cyanosis is usually noted early in life and is intensified by physical activity, crying or eating. Cyanosis tends to be persistent once it has appeared, although it may fluctuate in intensity. A general retardation of growth is frequently seen. Mental abilities do not appear to be particularly affected. Dyspnea and ease of fatigue are prominent symptoms. The assumption of the squatting posture appears to give these individuals relief and even very small children instinctively assume this position when they have overexerted themselves. Respiratory infections are common as is the occurrence of congestive heart failure.

Syncope with or without convulsions may occur. The presence of syncope tends to be a poor prognostic sign and, indeed, death may occur during such an episode. Because of the mixing of the two circulations, bacteremia and the development of cerebral abscess are also seen.

Physical examination may show cyanosis of the mucous membranes and also clubbing of the fingers or toes. A harsh systolic murmur often associated with the thrill is heard over the pulmonic area. The pulmonary second sound may be absent, diminished or normal.

X-ray examination of the heart shows the organ to be normal in size or slightly enlarged. The cardiac silhouette is classically bootlike in shape, characteristic of an enlarged right ventricle with diminution in the size of the common pulmonary artery as it leaves the right ventricle. Poststenotic dilatation of the pulmonary artery may be present with valvular or high infundibular obstruction. A clear pulmonary window may be observed when the pulmonary artery is small. The lung fields tend to appear quite clear and without the normal prominence of the pulmonary arterial markings. The absence of vascular markings in the outer half of the lung fields is particularly striking. The pulmonary artery and the hilum have decreased or absent pulsations. In adults, the pulmonary markings may not show the characteristic avascularity observed in children and infants. The aorta descends on the right in approximately 20 per cent of the subjects and can be demonstrated by barium swallow.

Angiocardiography will show simultaneous opacification of the aorta and right ventricle. The area of pulmonary obstruction and a right-to-left shunt may be seen on injection of contrast medium directly into the right ventricle through a catheter or by intravenous angiocardiography.

Cardiac catheterization shows high right ventricular pressures and diminished pressure in the pulmonary artery. The catheter may pass into the aorta through the inter-ventricular septal defect. The right ventricular blood may show an increased oxygenation from the ventricular communication.

Tetralogy of Fallot is quite common and it has been estimated that approximately 70 per cent of children over two years of age who demonstrate a congenital lesion associated with cyanosis have tetralogy of Fallot. The prognosis depends on the relation of the severity of the various defects to the degree of compensatory mechanism present. The vast majority of these patients die in infancy or early childhood with progressive cyanosis, polycythemia and syncope. A few patients will survive to relatively late childhood and a still smaller number will live to adult life. Those who have severe lesions tend to have difficulty in infancy.

The operative risk in such patients is high and the earlier that operation must be performed because of progressive signs or symptoms, the higher is the mortality rate. Operative intervention in patients younger than two years carries an over-all risk of approximately 25 per cent. In patients past the age of three years, the operative mortality rate is under 5 per cent. Successful operation can be expected to eliminate the cyanosis and to permit degrees of activity which were previously not possible.

Early procedures for the amelioration of tetralogy of Fallot were based upon the delivery of increased amounts of unoxygenated blood to the pulmonary artery by the production of a shunt between the aorta or one of its branches and the pulmonary artery. These procedures were the subclavian-to-pulmonary-artery shunt and the direct aortic-pulmonary shunt. These procedures are of historical interest and are still used in selected instances. Total correction of tetralogy of Fallot by open operation is the procedure of choice (Fig. 7).

This can be accomplished by inflow occlusion under hypothermia with localized aortic perfusion with oxygenated blood or by the customary cardiac by-pass. By means of the standard method, the inflow is devi-

stress. With the development of high pulmonary arterial pressures over prolonged periods, reversal of the shunt may occur and cyanosis may become permanent. The heart is usually enlarged and the characteristic systolic murmur is best heard over the second or third left intercostal space. The murmur of an atrial septal defect is not entirely characteristic and may vary widely in intensity. The pulmonic second sound tends to be loud because of the increased pulmonary flow and increased pulmonary pressure. Fixed splitting of the pulmonic

strain. P waves are usually prominent and right bundle branch block of varying degree is the rule in defects of the secundum type. Vectorcardiograms are usually characteristic in primum lesions.

X-ray films of the heart show enlargement of the right atrium and right ventricle. The pulmonary artery and pulmonary vascular markings are prominent and pulsations of the secondary vessels are notable. Angiocardiography shows refilling of the right atrium from the left. In the presence of a pure left-to-right shunt, contrast medium cannot be visualized to pass from the right to the left side.

Cardiac catheterization is usually helpful to make certain no additional lesion is present and to determine the volume of the shunt. The catheter may pass directly into the left atrium or left ventricle, or a left-to-right shunt may be evident by increased oxygenation in the right atrium. The catheter can also enter the pulmonary veins, particularly those on the right. Entrance of the catheter into the pulmonary veins does not necessarily indicate anomalous venous drainage, although abnormalities of the pulmonary venous drainage are commonly associated with the atrial septal defect. By calculation of the right and left ventricular outputs, one may determine the amount of blood which is shunted per minute. In many patients the right ventricular output may be three or more times that of the left. Dye dilution or nitrous oxide techniques permit determination of the site of the shunt and quantitation of the volume of shunt.
